1. ABSTRACT

Erythropoiesis is a dynamic complex multistep process going from committed erythroid progenitors to erythroid precursors and circulating mature red cells. Erythroid maturation is strictly dependent on EPO signaling cascade. EPO physically interacts with its receptor (EPO-R), which expression is downregulated after the basophilic erythroblasts stage. Binding of EPO to EPO-R results in conformational change and it requires the activation of Jak2, as primary kinase. STAT5 is master of erythropoiesis and it resides in cytoplasm. In response to EPO signaling, it binds phospho-tyrosine (Tyr) residues in the nucleus, initiating the transcription of several genes important in terminal erythroid differentiation. Giving the importance of Jak2 kinase as initiator of the EPO signaling cascade, additional kinases, such as Lyn, a Src family kinase, has been described to participate to EPO pathway. Lyn is able to phosphorylate EPO-R, Jak2 itself and STAT5. The activation of EPO/Jak2 signaling pathway is associated with production of reactive oxidative species (ROS), which are also generated by a large amount of iron imported into the cells during heme biosynthesis. During erythropoiesis, ROS might function as second messenger by modulating intracellular signaling pathways. Fyn, a Src kinase, has been previously reported to participate in intracellular signaling pathways in response to ROS in various cell types.

Here, we explore the potential contribution of Fyn to normal and stress erythropoiesis by studying 2-4 months-old Fyn knockout mouse strain (Fyn−/−) and C57BL/6j as wild-type controls. Fyn−/− mice showed a mild compensated microcytic anemia associated with signs of dyserythropoiesis. Increased ROS levels and Annexin-V+ cells were presented in all Fyn−/− erythroblast subpopulations compared to wild-type, suggesting a possible reduction in the efficiency of erythropoietin (EPO) signaling pathway in the absence of Fyn. Indeed, in Fyn−/− erythroblasts we observed a reduction in Tyr-phosphorylation state of EPO-R associated with a compensatory activation of Jak2 without major change in Lyn activity. A reduction in STAT5 activation resulting in down-regulation of Cish, a known direct STAT5 target gene, was noted in Fyn−/− erythroblasts. This was paralleled by a reduction in GATA1 and increased HSP70 nuclear translocation compared to wild type, supporting a higher cellular pro-oxidant environment in the absence of Fyn. Using the vitro cell forming colony unit assay, we found a lower CFU-E and BFU-E cells production, which once again was associated with decreased activation of EPO mediated cascade in the absence of Fyn. To explore the possible role of Fyn in stress erythropoiesis, mice were treated with recombinant EPO, phenylhydrazine (PHZ) or doxorubicin (Doxo). Fyn−/− mice showed a low response to EPO compared to wild-type animals and prolonged anemia after either PHZ or Doxo treatment with a delayed hematologic recovery compared to wild-type mice. When we analyzed the expression of a battery of ARE-genes related to oxidative response such as catalase, Gpx, heme-oxygenase 1 and peroxiredoxin-2, we noted up-regulated expression of these genes in sorted Fyn−/− erythroblasts compared to wild-type cells. In agreement, we observed increased activation of the redox-sensitive transcriptional factor Nrf2 targeting ARE-genes, whose regulation has been previously linked to Fyn. In fact, Nrf2 is switched-off by Fyn, ubiquitylated and delivered to the autophagosome by the p62 cargo protein. In Fyn−/− sorted erythroblasts, we observed (i) accumulation of p62 in large clusters; and (ii) reduction of Nrf2-p62 complex compared to wild-type cells. To address the question whether the perturbation of Nrf2-p62 system results in impairment of autophagy in the absence of Fyn, we used LysoTracker to explore late phases of autophagy. Lysosomal progression was defective in Fyn−/− reticulocytes and it was associated with accumulation of p62 during in vitro reticulocyte maturation. These data indicate that the absence of Fyn blocks the Nrf2 post-induction response to oxidation, resulting in impaired autophagy. To validate our working hypothesis, we treated Fyn−/− mice with Rapamycin, an inducer of autophagy. In Fyn−/− mice, Rapamycin treatment resulted in decrease dyserythropoiesis, ROS levels and Annexin V+ cells, associated with reduction in accumulation of p62 in Fyn−/− erythroblasts. Collectively, our data
enabled us to document a novel role for Fyn in erythropoiesis, contributing to EPO-R activation and harmonizing the Nrf2-p62 adaptive cellular response against oxidation. Future studies will be designed to further characterize the signaling pathways intersects by Fyn in normal and diseased erythropoiesis.
2. ABBREVIATIONS

ALA: δ aminolevulinic acid
ALAS: δ aminolevulinic acid synthase
AMPK: AMP activated protein kinase
ARE: antioxidant responsive element
Atg 3: autophagy related protein 3
Atg 4: autophagy related protein 4

Atg 101: autophagy related protein 101
BFU-E: burst forming unit-erythroid
BMMC: bone marrow derived mast cell
BMPR: bone morphogenetic protein receptor
β-thal: β-thalassemia
CFU-E: colony forming unit erythroid
CML: chronic myelogenous leukemia
CPgenIII: coproporphynogen III
DOXO: doxorubicin
EKLF: erythroid Kruppel like factor
EPO: erythropoietin
EPO-R: erythropoietin receptor
ERFE: erythroferrone
ERK: extracellular signal regulated kinase
FECH: ferrochelatase
FIP200: FAK family interacting protein of 200 KDa
FOXO 3a: forkhead box 0 3a
Fpn: ferroportin
GAPDH: glyceraldehyde 3-phosphate dehydrogenase
G6PD: glucose-6-phosphate dehydrogenase
Hamp: hepcidin
HBB: hemoglobin B
HBA: hemoglobin A
HistH3: histone H3
HO-1: heme oxygenase 1
Hp: haptoglobin
HSC: hematopoietic stem cell
HSP70: heat shock protein 70
hVps34: class III phosphoinositide 3 kinase
IL-6: interleukin 6
IRE: iron responsive element
IRP: iron responsive protein
Keap1: Kelch like ECH associated protein 1
KIR: Keap1 interacting region
LC3: microtubule associated protein 1A/1B light chain
LDH: lactate dehydrogenase
LIR: LC3 interacting region
mTOR: mammalian target of rapamycin
NAC: N-acetyl cysteine
NQO1: NADPH dehydrogenase quinone 1
Nrf2: nuclear factor (erythroid derived 2) like 2
P: phospho
Pop I: pro-erythroblasts
Pop II: basophilic erythroblasts
Pop III: polychromatic erythroblasts
Pop IV: orthochromatic erythroblasts
PHZ: phenylhydrazine
PPIX: protoporphyrin IX
Prx 1: peroxiredoxin 1
Prx 2: peroxiredoxin 2
PV: polycythemia vera
Rapa: rapamycin
RBC: red blood cell
ROS: reactive oxygen species
SFK: src family kinase
SH1: src homology 1
SH2: src homology 2
SH3: src homology 3
SOD-1: superoxide dismutase 1
TB: total bilirubin
Tyr: tyrosine
TMPRSS6: transmembrane protease serine 6
TPO: thrombopoietin
ULK 1: UNC 51 like kinases 1
3. INTRODUCTION

3.1 Erythropoiesis

Erythrocytes transport and exchange O₂/CO₂, participating to key processes in cellular homeostasis and tissue function(s). In the peripheral circulation, red cells survive 120 days, based on their ability to go through the narrow capillaries on microcirculation system. Aged erythrocytes (i.e.: red cell membrane oxidation, lipid peroxidation) are efficiently removed by macrophages mainly localized in spleen. Thus, erythropoiesis plays a crucial role to ensure the constant renewal of erythroid population.¹

During development, a first wave of erythropoiesis, described as primitive erythropoiesis, begins in the yolk sac, characterized by large and nucleated cells. Subsequently, definitive erythropoiesis, in the developing fetal liver, produces small-enucleated cells, which will then occur in the bone marrow of adult.¹

Erythropoiesis is a dynamic complex multistep process going from committed erythroid progenitors to erythroid precursors and circulating mature red cells (Fig. 1).²

![Fig. 1: The process of erythropoiesis](modified from Palis J. Primitive and definitive erythropoiesis in mammals. Front. Physiol. 2014; 5:3)

Erythropoiesis is divided into 3 phases: early erythropoiesis, late erythropoiesis, corresponding to terminal erythroid differentiation, and reticulocyte maturation. Early erythropoiesis refers to the process by which multi-potential hematopoietic stem cells (HSC) proliferate and differentiate into committed erythroid progenitors.² The first
erythroid-specific progenitor is the burst forming unit-erythroid (BFU-E), through processes influenced by several multipotent cytokines, such as IL-3 or SCF. The BFU-Es expand and develop into erythropoietin (EPO)-responsive colony forming unit-erythroid (CFU-E), which further expand and differentiate into pro-erythroblasts.³

Terminal erythroid differentiation begins with morphologically recognizable pro-erythroblasts, which subsequently undergo sequential mitoses to become basophilic, polychromatic, and orthochromatic erythroblasts that enucleate to become reticulocytes. During terminal erythroid differentiation, several changes occur, including decrease in cell size, hemoglobinization, increased chromatin condensation, and enucleation. In addition, terminal differentiation is also accompanied by dramatic changes in the expression, as well as assembly, of membrane proteins.³⁻⁵

Erythroid maturation is strictly dependent on EPO signaling cascade.⁵⁻⁶ EPO physically interacts with its receptor (EPO-R), which expression is downregulated after the basophilic erythroblasts stage.⁷ Binding of EPO to EPO-R results in EPO-R conformational change and it requires the activation of Jak2, as primary kinase. Jak2 phosphorylates EPO-R, resulting in activation of multiple signaling pathways such as (I) the STAT5-BclXL system, involved in maturation and survival of erythroid precursors; and (II) the PI3-Kinase/Akt pathway,⁸⁻¹⁰ promoting both anti-apoptotic and proliferation signals.⁴

STAT5 is a master of erythropoiesis and it resides in cytoplasm. In response to EPO signaling, it binds phospho-tyrosine (Tyr) residues (Y343) on EPO-R cytoplasmic tail. STAT5 is then Tyr-phosphorylated and it translocates into the nucleus, initiating the transcription of several genes important in terminal erythroid differentiation.¹¹⁻¹⁴ This includes genes involved in suppression of cytokine signaling (Cish and Socs3) or in epigenetic regulation (Suv420h2).¹⁵⁻¹⁶

Recent studies have shown that mice genetically lacking STAT5 develop anemia, due to ineffective erythropoiesis, associated with a blunted response to erythropoietic stress. A reduction in Bcl-XL expression has been documented in STAT5⁻/⁻ mice, leading to decrease survival of early stage erythroblasts, further supporting the important role of STAT5 in normal and stress erythropoiesis.¹¹⁻¹⁴ Abnormalities in Jak2/STAT5 signaling pathway have been described in pathologic erythropoiesis such as β-thalassemia (β-thal) or Polycythemia Vera (PV).¹⁷
β-thal is an inherited red cell disorder characterized by reduced or absent production of β-globin chains. Ineffective erythropoiesis is one of the hallmarks of β-thal, characterized by (i) block in cell differentiation and expansion of erythroid precursors; (ii) severe oxidation mainly due to accumulation of free alpha chains; (iii) apoptosis of polychromatophilic erythroblasts. Extramedullary erythropoiesis and iron overload are additional elements related to the ineffective erythropoiesis, contributing to clinical severity of β-thal. Increased activation of Jak2/STAT5 axis has been shown in β-thal. Evidences in a mouse model for β-thal suggest Jak2/STAT5 axis as possible therapeutic target in β-thal. Ongoing phase II trial with ruxolitinib (NCT02049450), a Jak2 inhibitor, in regularly transfused β-thal patients has shown promising results in reducing extramedullary erythropoiesis and splenomegaly.

Giving the importance of Jak2 kinase as initiator of the EPO signaling cascade, additional kinases, such as Lyn, a Src family kinase, has been described to participate to EPO pathway. Lyn is able to phosphorylate EPO-R, Jak2 itself and STAT5 (see also section 1.2.1).

The activation of EPO/Jak2 signaling pathway is associated with production of reactive oxidative species (ROS), which are also generated by a large amount of iron imported into the cells during heme biosynthesis. In erythropoiesis, ROS may function as second messenger through the transient oxidation of cysteine residues on signaling targets, further contributing to increase the complexity of signal transduction in response to EPO. To ensure cell survival, proliferation and differentiation, the control of oxidative stress is crucial during erythropoiesis. This is supported by abnormalities of erythropoiesis reported in mice genetically lacking antioxidant or cytoprotective systems, such as Peroxiredoxin 2 (Prx2) or Superoxide Dismutase 1 (SOD1). In β-thal mice, our group has recently shown the importance of the interplay between Prx2 and the redox-sensitive transcription factor, Nrf2 (Nuclear factor (erythroid-derived 2)-like 2) in supporting β-thal pathologic erythropoiesis.

In response to oxidation, Nrf2 binds the Antioxidant Response Element (ARE) region of genes encoding for anti-oxidant or cytoprotective systems, such as heme oxygenase (HO-1), NADPH dehydrogenase quinone 1 (NQO1) or Prxs. Studies in β-thal erythropoiesis have highlighted the importance of another redox-related transcriptional factor: FOXO3a. FOXO3a belongs to the Forkhead Box O
(FoxO) family of transcription factors and responds to oxidative stress by the upregulation of ROS scavenging enzymes such as Superoxide Dismutase 2 (SOD2) or catalase. Mice genetically lacking FOXO3a are extremely sensitive to exogenous oxidative stress, such as that induced by phenylhydrazine (PHZ).

Collectively, these studies indicate the importance of the modulation of intracellular signal transduction during erythropoiesis as well as the adaptive mechanisms activated in response to oxidation. Although progresses have been made in characterization of signaling pathways and cell protective machinery during erythroid maturation, much still remain to be investigated in normal and pathological erythropoiesis.

3.1.2 Erythropoiesis and iron homeostasis
Iron is an essential element in cellular homeostasis and it is involved in redox controlled reactions, required in enzymatic cascade as well as in signal transduction pathways. Since the large part of iron is required in hemoglobin synthesis, erythropoiesis deeply affects iron metabolism. Studies in both acquired and inherited disorders characterized by either iron-deficiency or iron-overload have highlighted new mechanisms involved in iron homeostasis.

3.1.3 Hepcidin systemic iron homeostasis
Hepcidin (Hamp) is the master regulator of iron homeostasis. Hamp is mainly synthesized by hepatocytes. Hamp inhibits the transfer of dietary iron from duodenal enterocytes to plasma, the release of recycled iron from macrophages, predominantly in the spleen and the release of stored iron from hepatocytes. This cascade is related to the functional crosstalk between Hamp and its receptor ferroportin (Fpn), resulting in decreased iron release from cells to plasma and extracellular fluid.
Hamp expression is affected by: (I) iron levels or inflammation as stimulatory factors; (II) erythropoietin-stimulated expansion of erythroid precursors as inhibitory factor (Fig. 2).\textsuperscript{31}

Transferrin-bound iron concentrations contributes to regulation of Hamp expression. This regulatory pathway involves the bone morphogenetic protein receptor (BMPR) complex that signals predominantly through the SMAD4 pathway towards Hamp.\textsuperscript{31-32} BMP6 binding to BMPR, limits further intestinal iron absorption and release of iron from macrophage stores. Hemojuvelin (also known as HFE2), is another iron-specific ligand playing a role in Hamp expression. Hemojuvelin interacts with both BMPs and the BMPR, and it is negatively regulated through specific proteolytic cleavage by transmembrane protease serine 6 (TMPRSS6; also known as matriptase 2).\textsuperscript{31-32} Finally, interleukin-6 (IL-6) is also involved in Hamp expression in response to inflammatory storm.\textsuperscript{31-32} IL-6 activates the Jak2/STAT3 pathway inducing Hamp expression. Our group has recently shown that the absence of Prx2 results in perturbation of IL6 independent STAT3 activation towards Hamp expression, highlighting the novel role of Prx2 in iron homeostasis.\textsuperscript{33}
Progresses in the knowledge of the functional link between iron homeostasis and pathologic erythropoiesis has allowed the identification of Erythroferrone (ERFE).\textsuperscript{34} ERFE suppresses Hamp expression through a still unknown mechanism, possibly involving the BMP/SMAD signaling pathway.\textsuperscript{35-36}

3.1.4 Erythropoiesis and heme

Heme biosynthesis is another crucial event in erythroid hemoglobinization. In all cells, heme synthesis occurs through 8 enzymatic reactions, divided between mitochondria and cytosol compartments. During erythropoiesis, heme synthesis increases with cell differentiation and it is tightly coordinated with iron acquisition and globin gene synthesis.\textsuperscript{37-40}

In heme biosynthesis, the first step is the condensation of succinyl-CoA and glycine to form δ-aminolevulinic acid (ALA) in mitochondrial matrix. This reaction is catalyzed by ALA synthase (ALAS), which is considered a rate-limiting event. There are two isoforms of ALAS, ALAS1 and ALAS2, which are encoded by separated genes. Alas1 gene is located on chromosome 3 and it is ubiquitously expressed. It plays an important housekeeping function in providing heme in non-erythroid tissues.\textsuperscript{37-40} Otherwise, Alas2 gene is located on the X-chromosome and it is expressed exclusively in erythroid cells. Alas2 expression strongly increases during the late stages of erythroid differentiation and it is essential for terminal maturation of red cells.\textsuperscript{41-42} The expression of Alas2 is regulated by erythroid-specific transcription factors, such as GATA-1.\textsuperscript{43} At post-transcriptional level, Alas2 expression is sensitive to iron intracellular levels. Alas2 transcript contains a 5′ iron responsive element (IRE) that interacts with iron responsive proteins (IRPs), linking the regulation of heme biosynthesis to the availability of iron in erythroid cells.

ALA is then exported to the cytosol, where it is converted to coproporphyrinogen III (CPgenIII). Then, CPgenIII is imported back to mitochondria and it is converted to protoporphyrin IX (PPIX). Finally, ferrous iron (Fe\textsuperscript{2+}) is incorporated into PPIX to form heme in mitochondrial matrix, a reaction catalyzed by ferrochelatase (FECH) (Fig. 3).\textsuperscript{44}

Recently, two heme exporters have been described: (I) FLVCR1a, localized in cellular plasma membrane; (II) FLVCR1b, localized in mitochondria plasma membrane. The coordinated expression of FLVCR1a and FLVCR1b contributes to control the size of the
cytosolic heme pool required to sustain metabolic activity during the expansion and hemoglobinization of erythroid cells (Fig. 3).\textsuperscript{38-40,45,46} 

\section*{3.2 Src family kinases (SFKs)}

Src family kinases (SFKs) are a group of cytoplasmatic Tyrosine (Tyr)-kinases, which are involved in signal transduction pathways important in cell homeostasis.\textsuperscript{47} SFKs comprises 9 members of kinases (Src, Fgr, Hck, Lyn, Yes, Lck, Fyn, Frk and Blk) some of which are expressed in a variety of cell types, whereas other are primarily expressed by hematopoietic cells, such as Lyn, Fyn or Src.\textsuperscript{48} SFKs exhibit a conserved domain organization that allows them to establish physical association with receptors and different proteins located upstream/downstream in signal cascades.\textsuperscript{48} All family members are characterized by an N-terminal unique region (50-70 residues) of high variability always encompassing a myristoylation and sometimes a palmitoylation site, flowed by the \sim 50 amino acid Src homology 3 (SH3) domain, which
directs specific association with proline rich motifs related to the PXXP consensus.\textsuperscript{49-54}

This is followed by \~ 100 amino acid Src homology 2 (SH2) domain which provides the interaction with phosphor-Tyr motifs and confers recognition and regulatory proprieties. The last domain is the kinase (~ 300 residues), or catalytic domain, or Src homology 1 (SH1), responsible for the enzymatic activity (Fig. 4).\textsuperscript{49-54}

---

**Fig. 4:** Domain organization of the SFKs

SFKs have two Tyr-motifs that regulate their activity in opposing ways. There is the activation loop (A-loop) residue, between the N-lobe and the C-lobe of the kinase domain, that is Tyr-phosphorylated in the fully active configuration, while the C-terminal Tyr-motif is phosphorylated in the fully inactive structure. This latter can interact with its own SH2 domain, making phospho-Tyr tail relatively inaccessible to phosphatase catalysis, inactivating SFK. It is likely that the combined interactions of the SH3 and the SH2 domains stabilize the overall inactive SFK’s configuration through the synergic effects of the two domains. Tyr-phosphorylation of the A-loop site has been detected in the most highly active forms of SFKs and seems to be important for the maximal kinase activity possibly deleting the auto-inhibitory SH3/SH2 intramolecular interactions. This phosphorylation is likely to be mediated by a trans-autophosphorylation, indicating that SFK members can crosstalk each other through the phosphorylation of the A-loop site. Thus, SFKs might be present as: 1) fully closed inactive form due to the intra-molecular SH3/SH2 interactions, a phosphorylated C-tail and an unphosphorylated A-loop; 2) partially active form in which the SH3 and/or SH2 interactions are disrupted, but the A-loop is not phosphorylated; 3) fully active form with the A-loop phosphorylated with or without SH3/SH2 association displacement. The autophosphorylation site of SFKs, plays a pivotal role when SFK is unphosphorylated, forming a short α-helix that prevents substrate binding and sequesters the A-loop Tyr. This makes the A-loop unavailable for phosphorylation, stabilizing the inactive kinase conformation. Otherwise, when the A-loop is phosphorylated, the Tyr forms a salt bridge with a conserved arginine that helps stabilizing the enzymatic active SFK configuration.

3.2.1 SFKs and erythropoiesis
Among SFKs, Lyn has been recently involved in EPO signaling cascade. Lyn targets specific Tyr-residue on the cytoplasmic tail of Epo-R, contributing to the signaling events involved in erythroid maturation and differentiation. Mouse models either lacking Lyn (Lyn<sup>−/−</sup>) or displaying hyperactive Lyn (Lyn<sup>up/up</sup>), show abnormalities in baseline erythropoiesis and in stress erythropoiesis.

Studies in these mouse models have allowed the identification of signaling pathways intercrossed by Lyn such as, GAB2/Akt/FOXO3 acting as pro-survival system or ERK1/2 (extracellular-signal-regulated kinase 1/2) as pro-apoptotic signal.64-67 Lyn−/− mice show reduced STAT5 activity, which results in decreased expression of BclXL, a molecule with anti-apoptotic function in erythropoiesis.64-67 In addition, Lynup/up erythroblasts display increased proteolytically degradation of EPO-R, suggesting an accelerated EPO-R turnover. This is associated with elevated Jak2 activation partially independent from EPO stimulation. Increased EKLF and STAT5 phosphorylation has been noted in Lynup/up erythroblasts, indicating possible downstream compensatory mechanism to constant activation of Lyn during erythropoiesis in this mouse strain.68-70 Finally, perturbation of Lyn function also affects
two master systems in erythropoiesis, GATA-1 and EKLF (Erythroid Kruppel-like factor).\textsuperscript{64-67}

3.3 Fyn is an emerging SFK

Fyn is another member of SFKs. Fyn is primarily localized to the cytoplasmic leaflet of the plasma membrane, where it phosphorylates Tyr-residues on key targets involved in a variety of different signaling pathways.\textsuperscript{71} This is functional to either regulate target proteins activity and/or generate a docking site on target proteins, allowing the recruitment of other signaling molecules.\textsuperscript{72} Fyn is important in cell growth and survival, cell adhesion, integrin-mediated signaling, cytoskeletal remodeling, cell motility, immune response and axon guidance.\textsuperscript{71}

The large part of available studies on mice genetically lacking Fyn are limited to neurobiology and brain system.\textsuperscript{72-74}

3.3.1 Fyn and hematopoiesis

In different blood cells and during hematopoiesis, recent studies have highlighted the role of Fyn as positive mediator of STAT5 function. In mast cell, Fyn is required for FcεRI-mediated STAT5 activation with possible additional role in stabilization of unphosphorylated STAT5.\textsuperscript{75-78} Studies on Fyn\textsuperscript{-/-} bone marrow-derived mast cells (BMMCs) reveal abnormalities of STAT5 activation, leading to impairment of mast cells degranulation.\textsuperscript{75} Involvement of Fyn in STAT5 activation has been also documented in chronic myelogenous leukemia (CML).\textsuperscript{79} In CML, Fyn has been proposed to contribute to the cyclophosphamide cell resistance, suggesting Fyn as a possible new therapeutic target in CML.\textsuperscript{79}

Fyn also participates to thrombopoietin (TPO)-induced cascade during \textit{in vitro} megakaryopoiesis. Thus, Fyn may play a pivotal role as an additional kinase to the canonical TPO/Jak2 pathway in megakaryopoiesis.\textsuperscript{80-82}
3.3.2 Fyn is a redox sensor

In different cell types, growing evidence indicate Fyn as primary redox sensor in oxidation-induced signaling pathway.83-84 Fyn might act as regulatory nexus between oxidation and signal transduction such as in its interaction with Nrf2. In fact, Fyn has been involved in post-induction regulation of the redox-sensitive transcription factor Nrf2.85-86 In presence of a severe cellular oxidative stress, Nrf2 translocates into the nucleus activating the expression of acute phase defensive genes.85-86 Then, Nrf2 is switched-off by Fyn, which phosphorylates Tyr-568 on Nrf2, resulting in its nuclear export and ubiquitylation.85-86 Mutagenesis experiments have shown that mutation of Tyr-213 on Fyn affects both nuclear localization and inactivation of Nrf2, increasing cell susceptibility to death.85-86 It has been reported that the prolonged activation of Nrf2 results in accumulation of polyubiquitylated proteins with an imbalance between protein synthesis and protein degradation.87-88 In various cell types, the persistence of Nrf2 signaling has been shown to be linked to impaired autophagy, a main cellular defensive process against the accumulation of damaged proteins.89

3.4 Autophagy and erythropoiesis

3.4.1 Autophagy

Autophagy is an efficient catabolic process responsible for the clearance of damaged organelles and proteins, contributing to cell homeostasis.90-93 Autophagy is generally activated by starvation or low levels of oxidation, whereas a more intense or prolonged oxidative stress overcomes autophagy flux and culminates in cell apoptosis.94,95 Autophagy starts with the engulfment of cellular materials by a double-layered structure, called the phagophore, that elongates, then closing to form the autophagosome. Finally, mature autophagosomes fuse with lysosomes, creating the autolysosome, where lysosomal hydrolytic enzymes degrade the cellular content (Fig. 5).96
The core machinery of autophagy consists of autophagy-related proteins (Atg), redox-sensitive proteins that might be either directly modulated by ROS (e.g.: Atg4 or Atg7) or transcriptionally regulated by oxidative stress (e.g.: p62). The functional connection between ROS and autophagy is also supported by the improvement of autophagy promoted by exogenous anti-oxidants, such as N-Acetyl-cysteine (NAC). Ulk1 phosphorylation is considered one of the main determinants and initiator of autophagy. The second key complex is the Beclin1/PI3K3, whose activity is dependent on ULK1 phosphorylation. Beclin1/PI3K3 drives the phagophore formation, followed by the recruitment of ubiquitin-like Atg5-Atg12-Atg16L complex that is required for autophagosome formation. This latter, together with Atg4 and Atg7, can activate the microtubule-associated protein 1A/1B light chain 3 (LC3) via lipidation with phosphatidylethanolamine (PE) to generate LC3-II. LC3-II anchors to inner and outer membranes of autophagosomal structures and it is required for phagophore expansion and fusion. In addition, LC3-II recruits proteins carrying the LC3-interacting region (LIR) to the autophagosome (Fig.6). The cargo elements are then directed by autophagy binding adaptor molecules, such as p62, to the terminal phase of autophagy. p62 is a multifunctional protein consisting of different...
domains and delivers polyubiquitinated cargoes to autophagy pathway through LIR domains and/or to proteasomal degradation via the N-terminal.\textsuperscript{96,104}

\textbf{3.4.2 Autophagy and erythropoiesis}

In erythropoiesis, autophagy plays a pivotal role in removal of organelles, such as ribosomes or mitochondria (mitophagy), as well as of damaged cytosolic proteins, allowing the generation of mature red cells.\textsuperscript{104,105} During erythropoiesis, ROS generation, nutrients deprivation and activation of AMP-activated protein kinase
(AMPK) inhibits the mammalian target of rapamycin complex 1 (mTORC1), which is a key repressor of autophagy.\textsuperscript{96,105} Studies on mouse models lacking members of the autophagy cascade have allowed the progress in the knowledge on autophagy during erythropoiesis. The table below summarizes the main results on autophagy and erythropoiesis based on the revision of the literature.

3.4.3 Autophagy and Nrf2

On steady state, Nrf2 is stabilized in the cytoplasm by Kelch-like ECH-associated protein 1 (Keap1).\textsuperscript{118,119} Under oxidation, Nrf2 is activated, dissociated from Keap1 and it translocates into the nucleus. When Nrf2 function is completed, Nrf2 migrates into the cytoplasm to be ubiquitylated. In the meantime, p62 interacts with Keap1 through the Keap1-interacting region (KIR), re-directing Keap-1 towards autophagic degradation (Fig. 8).\textsuperscript{96,120}
Thus, an interplay has been established between Nrf2 degradation and autophagy. p62 is involved in protein quality control mechanism. It binds to the Nrf2 shuttle protein Keap1, participating to Keap1 turnover. Thus, accumulation of p62 might be used as hallmark of impaired autophagy. Our group has recently reported a new molecular link between defective autophagy in terminal erythroid differentiation in patients with chorea-acanthocytosis. Once again, the accumulation of p62 was a marker of repressed autophagy in this model of diseased red cell.

5. AIM of the study

*Role of Fyn in normal and stress erythropoiesis*
6. MATERIALS AND METHODS

6.1 Drugs and chemicals
NaCl, Na$_3$VO$_4$, TRIS, Tween 20, EDTA, choline, MgCl$_2$, MOPS, Na$_2$HPO$_4$, KH$_2$PO$_4$, NaF, bicine, β-mercaptoethanol, benzamidine, glycine, glycerol, potassium cyanide, bromphenol blue, sodium dodecyl sulphate (SDS), hydrocortisone, albumin from bovine serum (BSA), May-Grunwald-Giemsa’s Azur-Eosin-Methylene Blue solution, were obtained by Sigma-Aldrich (Missouri, USA); dithiotreithol (DTT) was from Fluka (Buchs, Switzerland); protease inhibitor cocktail tablets were from Roche (Basel, Switzerland); 40% Acrylamide/Bis Solution, 37.5:1 was from BIO-RAD (California, USA); Luminata Forte Western Hrp solution was from Merck Millipore (Billerica, Massachusetts, USA); Prestained Protein Ladder, Triton X-100 and Temed were purchased from GE Healthcare Life Biosciences (Little Chalfont, UK); Annexin V Binding Buffer was from eBioscience (San Diego, USA); Dulbecco’s Phosphate Buffered Saline (DPBS) was from Lonza (Belgium); Iscove’s Modified Dulbecco’s Medium (IMDM), alpha-MEM, L-glutamine and Fetal Cow Serum (FCS) were from TermoFisher (Massachusetts, USA); Penicillin-Streptamycin and Amphotericin were from Euroclone (Milan, Italy); MethoCult™ M3234 was from StemCell Techologies (Milan, Italy).

6.2 Mice strains
We studied the following mouse strains: C57BL/6J as normal control (wild-type; WT) and Fyn$^{-/-}$ mice. Since in preliminary experiments we observed a more severe hematological phenotype in Fyn$^{-/-}$ female mice, we used female mice aging from 2 to 4 months old. Mouse blood was collected by retro-orbital venipuncture in anesthetized mice using heparinized capillares according to the general guidelines of local animal facility, University of Verona. Whenever indicated, anemia was induced by intraperitoneal injection of PHZ (40 mg/Kg body weight)$^1$ or Doxorubicin (0.25 mg/Kg body weight)$^2$. Blood was collected at day 2, 4, 8 and 14 after PHZ injection and at day 3, 6 and 9 after Doxorubicin injection. Spleen and bone marrow were collected at day 2, 4, 8 and 14 from PHZ injection and at day 9 after Doxorubicin injection. EPO (10 U/mice)$^3$ was intraperitoneally injected for 5 days. Blood was collected at day 6, 8 and 11 after EPO administration. Rapamycin (10 mg/Kg)$^4$ was intraperitoneally injected in
a single dose and spleen and bone marrow were collected after 1 week from Rapamycin administration.

6.3 Hematological parameters
Hematological parameters were evaluated on Siemens ADVIA 120 Hematology System. Hematocrit and hemoglobin were manually determined.\textsuperscript{5,6}

6.4 Flow cytometric analysis of mouse erythroid precursors and cell sorting of murine bone marrow erythroblasts
Cells from WT and Fyn\textsuperscript{-/-} mice bone marrows and spleens were collected in BEPS (BEPS: PBS 1X, BSA 1%, EDTA 2 mM, NaCl 25 mM). The erythroid precursors were analyzed as previously described\textsuperscript{7} using CD44-Ter119 strategy. Briefly, cells were centrifuged at 1,500 rpm for 5 min at 4°C and resuspended in the proper volume of BEPS. Cells were incubated first with CD16/32, to block Fc receptors, CD45-APC-Cy7, CD44-FITC, CD71-PE and Ter119-APC (eBioscience, San Diego, USA) antibodies for 30 min at 4°C in the dark. Cells were washed and centrifuged at 1,500 rpm for 5 min at 4°C, resuspended in BEPS and 7AAD, for cell viability, was added immediately before the analysis. All the analysis were performed with the flow cytometer FACSCanto\textsuperscript{TM} (Becton Dickinson, San Jose, CA, USA). Data were stored and processed using FACSDiva software (Becton Dickinson Immunocytometry System, San Jose, CA, USA). The biparametric scatter plots were analyzed with FlowJo software version vX.0.7 (Tree Star, Ashland, OR, USA) (Fig. 9).

\textbf{Fig. 9}: Example of cytofluorimetric scatter for erythroid precursors from WT mice. \textbf{Left panel}: analysis of CD44\textsuperscript{*} Ter119\textsuperscript{lo}\textsubscript{pop} corresponding to pro-erythroblasts. \textbf{Right panel}: analysis of CD44\textsuperscript{*}-Ter119\textsuperscript{hi} Pop II, III, IV, corresponding to basophilic, polychromatic and orthochromatic erythroblasts respectively.
Population III and IV corresponding to polychromatic and orthochromatic erythroblasts and total erythroblasts (CD44+Ter119+FSC\textsuperscript{high}) were sorted from bone marrow of both mouse strains as previously reported. Sorted cells were used for (i) morphological analysis of erythroid precursors on cytospin preparations stained with May Grunwald-Giemsa; (ii) immunoblot analysis and (iii) RT-PCR analysis. For immunoblot analysis the following specific antibodies were used: anti P-Ser473-Akt, anti Akt, anti P-Ser2448-mTOR, anti mTOR (Cell Signaling, Massachusetts, USA), anti P-Ser40-Nrf2, anti catalase, anti Nrf2, anti Prx1, anti Prx2, anti p62, anti Rab5 (Abcam, Cambridge, UK), anti Keap1 (Proteintech, Manchester, UK), anti GATA-1, anti HSP70, anti G6PD, anti NQO1 and GAPDH (Santa Cruz Biotechnology, Texas, USA) and HistH3 (Cell Signaling, Massachusetts, USA) as loading control. Whenever indicated we carried out immunoprecipitation (IP) experiments as previously reported. Briefly, 1.5*10^6 sorted CD44+Ter119+FSC\textsuperscript{high} cells from WT and Fyn\textsuperscript{-/-} were resuspended in Complete Bicine Solution (CBS: Bicine 25 mM, Triton X-100 1.5%, Na\textsubscript{3}VO\textsubscript{4} 1 mM, NaF 1 mM, EDTA 1 mM, in the presence of protease inhibitors) and underwent 3 cycles of freeze/thaw. The supernatant was collected and incubated with washed IP beads (Thermo Scientific, MA, USA) and phosphoTyr antibodies (PY99; Santa Cruz Biotechnology, Texas, USA and 4G10; Millipore, Massachussets, USA). The day after beads were spun down, washed with CBS without inhibitors and solubilized with SB2X+β for 1h at RT. Before loading gels, beads were heated at 60°C for 4 min. Filters were incubated overnight with anti EPO-R (Sigma-Aldrich, Missouri, USA), anti STAT5, anti Lyn (Santa Cruz Biotechnology, Texas, USA), anti Jak2 (Cell Signaling Technology, Danvers, USA) and anti IgG rabbit (GE Healthcare Life Sciences, Little Chalfont, UK) as loading control. Secondary anti-rabbit and anti-mouse antibodies were purchased from GE Healthcare Life Biosciences (Little Chalfont, UK). Images were acquired using Image Quant Las Mini 4000 Digital Imaging System (GE Healthcare Life Sciences, Little Chalfont, UK).

6.5 Annexin V analysis of mouse erythroid precursors

Analysis of apoptotic erythroblasts from WT and Fyn\textsuperscript{-/-} mice was carried out on the CD44-Ter119 gated cells using the Annexin-V PE Apoptosis detection kit (eBioscience, San Diego, CA, USA) following the manufacturer instructions. Flow cytometric analysis was carried out with the FACSCantoll\textsuperscript{TM} flow cytometer (Becton Dickinson, San Jose,
CA, USA). Data were stored and processed using FACSDiva software (Becton Dickinson Immunocytometry System, San Jose, CA, USA). The biparametric scatter plots were analyzed with FlowJo software version vX.0.7 (Tree Star, Ashland, OR, USA).

6.6 Analysis of ROS levels on different populations of erythroid precursors

The ROS levels of erythroid precursors from WT and Fyn<sup>−/−</sup> mice were determined using the General Oxidative Stress Indicator CM-H<sub>2</sub>DCFDA (LifeTechnologies, Carlsbad, CA, USA) on erythroid precursors as previously described<sup>9</sup> with minor changes. Briefly, CD44-PE, Ter119-APC, CD45-APC-Cy7 (eBioscience, San Diego, USA) stained cells, from mouse bone marrow, were incubated with CM-H<sub>2</sub>DCFDA (10 μM in PBS, BSA 1% at 37°C for 20 min). Cells were then washed once with PBS BSA 1%, stained in ice with 7-AAD and analyzed with the FACSCanto<sup>TM</sup> flow cytometer (Becton Dickinson, San Jose, CA, USA). Data were stored and processed using FACSDiva software (Becton Dickinson Immunocytometry System, San Jose, CA, USA). The biparametric scatter plots were analyzed with FlowJo software version vX.0.7 (Tree Star, Ashland, OR, USA).

6.7 Murine BFU-E and CFU-E assay

Incomplete MethoCult™ (M3234) media was thawed at room temperature (15 - 25°C) or overnight at 4°C. 0.2*10<sup>6</sup> cells from BM of WT and Fyn<sup>−/−</sup> mice were collected in Complete α-MEM (α-MEM, 1% Penicillin-Streptomicin, 1% Hydrocortisone, 1% nucleotides, Gentamicin 0,025 mg/L, Amphotericin 0,5 ug/mL) and then added to MethoCult™ media. Growth factors (SCF 50 ng/mL, IL-3 10 ng/mL and EPO 3U/mL) were added fresh every time to complete α-MEM. Media were vortexed to ensure all components were thoroughly mixed (let the tube stand for at least 5 minutes to allow the bubbles to rise to the top). MethoCult™ mixture containing cells was dispensed into sterile culture dishes. Empty wells were filled with sterile water. The plates were incubated at 37°C and 5% CO<sub>2</sub>. After 5 and 10 days, WT and Fyn<sup>−/−</sup> CFU-Es and BFU-Es, were picked up, counted and solubilize in CBS with inhibitors. We carried out IP experiments on WT and Fyn<sup>−/−</sup> CFU-Es. Briefly, 2*10<sup>6</sup> CFU-Es from WT and Fyn<sup>−/−</sup> were resuspended in CBS with inhibitors and underwent 3 cycles of freeze/thaw. The supernatant was collected and incubated with washed IP beads and phosphor-Tyr antibodies (PY99; Santa Cruz Biotechnology, Texas, USA and 4G10; Millipore, Billerica,
Massachusetts, USA). The day after beads were spun down, washed with CBS without inhibitors and solubilized with SB2X+β for 1h at RT. Before loading gels, beads were heated at 60°C for 4 min. Filters were incubated overnight with anti EPO-R (Sigma-Aldrich, Missouri, USA), anti STAT5, anti Lyn (Santa Cruz Biotechnology, Texas, USA), anti Jak2 (Cell Signaling Technology, Danvers, USA) and anti IgG rabbit (GE Healthcare Life Sciences, Little Chalfont, UK) as loading control.

6.8 In vitro maturation of reticulocytes from WT and Fyn−/− mice after PHZ treatment

WT and Fyn−/− mice were intraperitoneally injected with PHZ (40 mg/kg) at day 0, 1 and 3. One week after the first injection of PHZ, blood from WT and Fyn−/− mice was collected. Washed and packed RBCs from heparinized whole blood were used for (i) cytosol preparation, as previously described, (ii) LysoTrack and MitoTrack staining and (iii) in vitro maturation of reticulocytes. For in vitro maturation, blood was diluted 1:500 in 1.5 ml of maturation medium (60% IMDM, 2mM L-glutamine, 100U Penicillin-Streptomycin, 30% FCS, 1% BSA and 1X Amphotericin) and cultured in a 24-well tissue culture plate in a cell culture incubator at 37°C with 5% of CO₂ for 3 days.

6.9 MitoTracker and LysoTracker analysis on RBCs and cultured reticulocytes after PHZ treatment

RBCs and cultured reticulocytes from PHZ treated WT and Fyn−/− mice underwent lysosome and mitochondria staining using the Lysotracker Green DND-26 (ThermoFisher Scientific) and the MitoTracker Deep Red (ThermoFisher Scientific), following the manufacturer’s instructions. Cells were analyzed with the FACSCantoll™ flow cytometer (Becton Dickinson, San Jose, CA, USA). Data were stored and processed using FACSDiva software (Becton Dickinson Immunocytometry System, San Jose, CA, USA). The biparametric scatter plots were analyzed with FlowJo software version vX.0.7 (Tree Star, Ashland, OR, USA).
7. RESULTS

7.1 Fyn<sup>F</sup> mice display a mild mycroctic anemia

We first analyzed the hematological parameters of wild-type (WT) and Fyn<sup>F</sup> mice (Table 3). Fyn<sup>F</sup> mice showed a very mild hypochromic anemia as defined by reduction in hemoglobin (Hb) levels and lower mean corpuscular volume (MCV) (Table 3). This was associated with slight but significant increase in reticulocyte count in Fyn<sup>F</sup> mice compared to WT.

| TABLE 3. HEMATOLOGICAL DATA OF WT AND Fyn<sup>F</sup> MICE |
|---------------|-----------------|-----------------|
|               | WT mice          | Fyn<sup>F</sup> mice |
|               | (n=10)           | (n=10)          |
| Hct (%)       | 48.2 ± 1.3       | 46.1 ± 0.8*     |
| Hb (g/dl)     | 15.9 ± 0.6       | 14.3 ± 0.5*     |
| MCV (fl)      | 50.3 ± 0.4       | 46.5 ± 1.3*     |
| MCH (g/dl)    | 15.3 ± 0.3       | 14.8 ± 1.1      |
| CHCM (g/dL)   | 26.4±0.5         | 29.6 ± 1.4*     |
| RDW (%)       | 11.6 ± 0.3       | 13.2 ± 0.4*     |
| Retics (10<sup>3</sup> cells/uL) | 451± 40.7 | 559 ± 45* |

Hct: hematocrit; Hb: hemoglobin; MCV: mean corpuscular volume; MCH: mean corpuscular haemoglobin; CHCM: mean cellular hemoglobin concentration; RDW: red blood cell distribution width; Retics: reticulocytes; *p <0.05 compared to WT mice.

Increased total bilirubin (TB) and plasma lactate dehydrogenase (LDH) levels were observed in Fyn<sup>F</sup> mice compared to healthy controls (Fig. 1a). Up-regulation of haptoglobin (Hp) gene expression was found in liver from Fyn<sup>F</sup> mice (Fig. 1b, left panel); whereas, plasma Hp levels showed a trend to increase without reaching statistical significance compared to WT (Fig. 1b, right panel). No iron-overload was detected in either liver or spleen from Fyn<sup>F</sup> mice (Fig. 1c). Up-regulation of EPO mRNA
expression was found in Fyn\(^{-/-}\) mice (Fig. 1d). Collectively, these data suggest the presence of a very mild hemolytic compensated microcytic anemia in mice genetically lacking Fyn.

**Fig. 1**

(a): TB and plasma LDH levels. Data are presented as means±SD \((n=6)\); \(*p<0.05\) compared to WT mice [in collaboration with Prof E.Tolosano, University of Torin, Italy].

(b): RT-PCR expression of Hp on liver from WT and Fyn\(^{-/-}\) mice. Experiments were performed in triplicate. Error bars represent the standard deviations (means±SD); \(*p<0.05\) compared to WT mice. [in collaboration with Prof. A. Iolascon and Dr. L. De Falco, University Federico II, Naples]; Immunoblot analysis of Hp in WT and Fyn\(^{-/-}\) mice. (c): Iron staining (Pearl’s Prussian blue) in liver and spleen from WT and Fyn\(^{-/-}\) mice. One representative image from the other six with similar results is presented.

(d): RT-PCR expression of EPO on kidney from WT and Fyn\(^{-/-}\) mice. Experiments were performed in triplicate. Error bars represent the standard deviations (means±SD); \(*p<0.05\) compared to WT mice [in collaboration with Prof. A. Iolascon and Dr. L. De Falco, University Federico II, Naples]. TB, total bilirubin; LDH, lactate dehydrogenase; RT-PCR, real time polymerase chain reaction; Hp, haptoglobin; EPO, erythropoietin.
7.2 The absence of Fyn is associated with dyserythropoiesis, increased oxidative stress and low GATA-1 nuclear translocation

We carried out morphological analysis of sorted erythroblasts from WT and Fyn\(^{-/-}\) mice. As shown in Fig. 2a, signs of dyserythropoiesis mainly involving Pop II and Pop III were detected in Fyn\(^{-/-}\) mice compared to WT. This was associated with increased erythroid precursors (CD71\(^{+}\)Ter119\(^{+}\)cells; Fig. 2b) without evidences of extramedullary erythropoiesis. We then measured the generation of ROS in sorted erythroblasts from both mouse strains. We found higher ROS levels in Fyn\(^{-/-}\) erythroblasts compared to WT (Fig. 2c, upper panel). Increased amount of Annexin-V positive erythroblasts was found in Fyn\(^{-/-}\) mice (Fig. 2c; lower panel).
erythroblasts; Pop III, polychromatic erythroblasts; Pop IV, orthochromatic erythroblasts). Data are presented as means±SD (n=8); *p< 0.05 compared to WT mice. **Lower panel:** Annexin-V+ erythroblasts in populations II-IV from WT and Fyn−/− mice (Pop II, basophilic; Pop III, polychromatic; Pop IV, orthochromatic erythroblasts). Data are presented as means±SD (n=8); *p< 0.05 compared to WT mice. (d): Immunoblot analysis with specific antibody against GATA-1 and HSP70 on cytosolic and nuclear fraction of sorted CD44+Ter119+FSChigh cells. GAPDH and HistH3 were used as loading controls. One representative gel from three with similar results is presented. Densitometric analysis are reported in supplementary data. (e): RT-PCR expression of HBB major, HBB minor and HBA1 on sorted Pop III and Pop IV from WT and Fyn−/− bone marrow (Pop III, polychromatic erythroblasts; Pop IV, orthochromatic erythroblasts). Experiments were performed in triplicate. Error bars represent the standard deviations (means±SD [in collaboration with Prof. A. Iolascon and Dr. L. De Falco, University Federico II, Naples]. (f): TAU Gel Electrophoresis of α/β-globins from WT and Fyn−/− circulating red cells. ROS, reactive oxygen species; TAU, Triton-Acetic-Urea; RT-PCR, real time polymerase chain reaction.

β-thalassemia (β-thal; see also introduction section 3.1) is a human model of stress erythropoiesis and it is characterized by increased ROS levels and hyperactivation of Jak2-STAT5 signaling pathway. In β-thal erythropoiesis oxidation affects nuclear translocation of GATA-1, a key transcriptional factor involved in erythroid maturation events. Thus, we evaluated GATA-1 in Fyn−/− erythroblasts, we observed reduced GATA-1 nuclear translocation compared to WT (Fig. 2d). This was associated with increased HSP70 nuclear translocation, similarly to that described in β-thal erythroblasts. Indeed, a significant decrease in β-globin chain synthesis, was evident in Fyn−/− mouse erythroblasts (Fig. 2e). An accumulation of the α-globin chains (α-globin aggregates) was detected in circulating Fyn−/− red cells (Fig. 2f). These data suggest a possible reduced efficiency of EPO signaling cascade in the absence of Fyn.

7.3 The absence of Fyn is associated with reduced efficiency of EPO-signaling pathway

We then explored Jak2-STAT5 Tyr-phosphorylation state, which is strictly dependent on the efficiency of EPO signaling cascade. In sorted Fyn−/− erythroblasts, we observed reduced activation of EPO-R (decreased Tyr-phosphorylation state of EPO-R), compared to WT erythroblasts (Fig. 3a). This was associated with increased Jak2 compensatory activation, without major difference in Lyn functional state (Fig 3a). In sorted Fyn−/− erythroblasts, STAT5 activation was significantly decreased, as supported by down-regulation of Cish, an exclusively STAT5 regulated gene (Fig. 3b).
Using the vitro erythroid cell forming colony unit assay, we found a lower CFU-E and BFU-E cells production from Fyn−/− bone marrow cells in presence of standard EPO stimulation (3 U/ml) (Fig. 3c). This was again associated with decreased activation of EPO mediated signaling cascade in Fyn−/− CFU-E with compensatory hyperactivation of Jak2 (Fig. 3d). Since the absence of Fyn results in low efficiency of EPO signaling cascade, the hyperactivation of Jak2 may be related to increase ROS levels characterizing Fyn erythroblasts.

To better understand the role Fyn in EPO-signaling cascade, we treated both mouse strains with recombinant EPO (10 U/day for 5 days; red arrows in Fig. 4a). Increase of Hct and reticulocytes (as CD71+Ter119+ circulating cells) was blunted in Fyn−/− mice compared to WT animals (Fig. 4a). Collectively, these data indicate a reduction in the efficiency of EPO signaling pathway in the absence of Fyn.

**Fig. 3:** (a): Anti phosphor-Tyr immunoprecipitation analysis of Jak2-STAT5 signaling pathway on sorted CD44+Ter19+FSCint+ cells from WT and Fyn−/− mice. IgG were used as loading control. One representative gel from three with similar results is presented. Densitometric analysis are reported in supplementary data. (b): RT-PCR expression of Cish on sorted Pop III and Pop IV from WT and Fyn−/− bone marrow (Pop III, polychromatic erythroblasts; Pop IV, orthochromatic erythroblasts). Experiments were performed in triplicate. Error bars represent the standard deviations (means±SD); *p< 0.05 compared to WT mice. [in collaboration with Prof. A. Iolascon and Dr. L. De Falco, University Federico II, Naples]. (c): In vitro colony-forming unit assay of BFU-Es and CFU-Es from WT and Fyn−/− mice. Data are presented as means±SD (n=5); *p< 0.05 compared to WT mice. (d): anti phosphor-Tyr immunoprecipitation analysis of Jak2-STAT5 signaling pathway on CFU-Es from WT and Fyn−/− mice. IgG were used as loading control. One representative gel from three with similar results is presented. Densitometric
7.4 Fyn^-/- mice display a high sensitivity to PHZ or Doxorubicin induced stress erythropoiesis

We then treated both mouse strains with either PHZ (40 mg/Kg; red arrows in Fig. 4b) or Doxorubicin (0.25 mg/Kg; red arrow in Fig. 5a). In mice, PHZ is known to induce severe oxidation and acute hemolytic anemia, while Doxorubicin temporary represses erythropoiesis with ROS generation.\textsuperscript{1,2}

As shown in Fig. 4b, PHZ induced a similar marked drop in Hct levels in both mouse strains at day 2 after PHZ injection. In Fyn^-/- mice, we observed a delayed increase in Hct levels at day 4 and 8 compared to WT. The increase in reticulocyte count in PHZ treated Fyn^-/- mice was blunted compared to WT mice, showing a peak at day 8 after PHZ injection (Fig. 4b). As shown in Fig. 4c, we found increased levels of total erythroblasts in bone marrow and spleen from both mouse strains following PHZ injection. In Fyn^-/- spleen, the increase in erythroid precursors was blunted at day 4, with a compensatory increase at day 14 after PHZ administration (Fig. 4c, upper panel). In bone marrow, we observed a mild increase in total erythroblasts in both mouse strains at day 2 and 4 after PHZ injection (Fig. 4c, lower panel). Noteworthily, in Fyn^-/- mice we found a marked increase in bone marrow total erythroblasts at day 8 after PHZ, suggesting a possible compensatory mechanism in Fyn^-/- mice do to the lack of splenic response following PHZ treatment (Fig. 4c, lower panel). At day 4 and 8 after PHZ injection, the amount of Annexin-V^+ cells was higher in Fyn^-/- polychromatic and orthochromatic erythroblasts in both bone marrow and spleen compared to WT animals (data not shown).
In Fyn⁻/⁻ mice, Doxorubicin induced a more severe and prolonged anemia compared to WT. We also found a delay in reticulocytes response compared to Doxorubicin treated WT animals (Fig. 5a). Total erythroblasts were determined at day 9 after Doxorubicin administration in both spleen and bone marrow. In Fyn⁻/⁻ mice, we observed a significant reduction in both bone marrow and spleen erythroblasts, compared to vehicle treated controls (Fig. 5b). Increased amount of Annexin V⁺ polychromat and orthochromatic erythroblasts was observed at day 9 after Doxorubicin administration in Fyn⁻/⁻ mice compared doxorubicin treated WT animals (data not shown).

These data suggest an increased sensitivity of Fyn⁻/⁻ mice to stress erythropoiesis, further supporting the importance of Fyn in EPO signaling cascade.
Fig. 5: (a): Hematocrit (Hct) and reticulocyte count in WT and Fyn<sup>−/−</sup> mice after Doxorubicin injection (0.25 mg/kg; red arrow). Data are presented as means±SD (n= 5); *p< 0.05 compared to WT mice. (b): Analysis of total erythroblasts in bone marrow and spleen from WT and Fyn<sup>−/−</sup> mice after Doxorubicin injection. Data are presented as means±SD (n= 5). *p< 0.05 compared to WT mice. DOXO, doxorubicin; Hct, hematocrit.

7.5 Fyn<sup>−/−</sup> mice display increased Akt

Previous studies have shown that EPO-Jak2 pathway can activate Akt, which is also directly modulated by ROS (Fig. 6a).<sup>15</sup> Thus, we evaluated Akt function in sorted erythroblasts from both mouse strains. As shown in Fig. 6b, Fyn<sup>−/−</sup> mouse erythroblasts displayed increased active Akt (Ser 473) compared to WT cells (Fig. 6b). Activation of Akt might affect multiple targets involved in response to oxidation. Akt might (I) functionally interact with the redox sensitive transcriptional factor Nrf2, resulting in Nrf2 activation; or (II) activate mTOR, which phosphorylation represses autophagy.<sup>15,16</sup>
In Fyn<sup>−/−</sup> erythroblasts, we found increased activation of Nrf2 (Ser40) compared to WT cells, most likely related to the absence of Fyn as key post-induction regulator of Nrf2 (Fig. 6c). This was supported by up-regulation of ARE-genes for anti-oxidant and cytoprotective systems such as Catalase, G6PD, GPX1, HO-1 and Prx2 (Fig. 6d).
Immunoblot analysis with specific antibodies showed increased expression of the encoded proteins, validating the molecular data (Fig. 7).

![Fig. 7](image)

**Fig. 7**: Immunoblot analysis with specific antibodies against G6PD, HO-1, Prx2, Prx1 and NQO1 from WT and Fyn<sup>−/−</sup> sorted Pop III and Pop IV. GAPDH was used as loading control. One representative gel from three with similar results is presented. Densitometric analysis are reported in supplementary data.

### 7.6 In Fyn<sup>−/−</sup> mice, activation of mTOR impairs autophagy, leading to abnormalities on the in vitro reticulocyte maturation

Previous studies have shown that autophagy plays a key role in erythropoiesis, contributing to the correct maturation and differentiation of erythroid precursors (ref). Although modulation of mTOR during erythropoiesis is only partially known, mTOR is a key protein in autophagy and its activation by Akt represses autophagy. In Fyn<sup>−/−</sup> mouse erythroblasts, we found increased active mTOR (Ser2448) associated with accumulation of p62 and Rab5, both proteins involved in late phase of autophagy (Fig. 8a). Moreover, in Fyn<sup>−/−</sup> erythroblasts, we found accumulation of Keap1, the physiologic inhibitor of Nrf2 (Fig. 8a). These data suggest an impairment of autophagy processes during erythropoiesis in the absence of Fyn.

Since autophagy has been shown to be important during reticulocyte maturation, we analyzed in vitro reticulocyte maturation from PHZ treated mice. We found reduced Fyn<sup>−/−</sup> reticulocyte maturation compared to WT (Fig. 8b, left panel). This was associated with decreased lysosomal clearance, as shown by LysoTrack analysis, without major difference in mitochondrial clearance, as shown by MitoTrack analysis (Fig. 8b, right panel).
An accumulation of p62, was again detected in maturing reticulocytes in the absence of Fyn, further supporting the impairment of autophagy in Fyn$^{-/-}$ mice (Fig. 8c).

Fig. 8: (a): Immunoblot analysis with specific antibodies against p-Ser2448-mTOR, mTOR, p62, Keap1 and Rab5 from WT and Fyn$^{-/-}$ sorted CD44$^+$Ter119$^+$FSC$^{high}$ erythroblasts. GAPDH was used as loading control. One representative gel from three with similar results is presented. Densitometric analysis are reported in supplementary data. (b) (Left) Flow cytometric scatter of RBCs at day 0 and after 3 days of in vitro maturation from PHZ treated WT and Fyn$^{-/-}$ mice. One representative of 3 independent experiments with similar results. Data are shown as means±SD (n=3); *p< 0.05 compared to WT mice. (Right) Flow cytometry of RBCs at day 0 and after 3 days of in vitro maturation from PHZ treated WT and Fyn$^{-/-}$ mice intravitaly stained with LysoTracker and MitoTracker. One representative of 3 independent experiments with similar results. Data are shown as means±SD (n=3); *p< 0.05 compared to WT mice. (c): Immunoblot analysis with specific antibodies against p62 in RBCs at day 0 and after 3 days of in vitro maturation from PHZ treated WT and Fyn$^{-/-}$ mice. Catalase was used as loading control. One representative gel from three with similar results is presented. Densitometric analysis are reported in supplementary data.

7.7 The mTOR inhibitor Rapamycin unlocks autophagy and ameliorates erythropoiesis in Fyn$^{-/-}$ mice
We then treated both mouse strains with Rapamycin (10 mg/Kg), a known mTOR inhibitor, which has been shown to promote autophagy and beneficially impact stress erythropoiesis in other mouse models.\(^4\)

Rapamycin administration reduced total bone marrow Fyn$^{-/-}$mouse erythroblasts, while no significant effects were observed in control animals as previously reported.
A significant reduction in generation of ROS and in the amount of Annexin-V+ cells was found only in erythroid precursors from Fyn⁻/⁻ mice (Fig. 9b, 9c). In agreement with the activation of autophagy we observed decreased levels of p62 in Rapamycin treated Fyn⁻/⁻ erythroblasts compared to vehicle treated animals (Fig. 9d). No major change was observed in hematologic parameters as previously reported.⁴ These data suggest that the inhibition of mTOR unlocks autophagy and ameliorates erythropoiesis in Fyn⁻/⁻ mice.

Fig. 9: (a): Analysis of total erythroblasts in WT and Fyn⁻/⁻ bone marrow (Ter119-CD44 based gating) treated with either vehicle or Rapamycin. Data are presented as means±SD (n=5); *p<0.05 compared to WT mice; °p<0.05 compared to vehicle treated mice (b): ROS levels of erythroblast in populations II - IV from WT and Fyn⁻/⁻ mice treated with either vehicle or Rapamycin (Pop II, basophilic erythroblasts; Pop III, polychromatic erythroblasts; Pop IV, orthochromatic erythroblasts). Data are presented as means±SD (n=5); *p<0.05 compared to WT mice; °p<0.05 compared to vehicle treated mice. (c): Annexin-V+ erythroblasts in populations II-IV from WT and Fyn⁻/⁻ mice treated with either vehicle or Rapamycin. (Pop II, basophilic; Pop III, polychromatic; Pop IV, orthochromatic erythroblasts). Data are presented as means±SD (n=5); *p<0.05 compared to WT mice; °p<0.05 compared to vehicle treated mice. (d): Immunoblot analysis with a specific antibody against p62 from Fyn⁻/⁻ sorted CD44⁺Ter119⁻FSC<sup>N/P</sup> erythroblasts treated with either vehicle or Rapamycin. Catalase was used as loading control. One representative gel from three with similar results is presented. Densitometric analysis are reported in supplementary data.
8. DISCUSSION

Here, we found a novel role of Fyn in EPO-mediated signaling pathway in normal and stress erythropoiesis. Fyn affects EPO-R and STAT5 Tyr-phosphorylation state, without change in Lyn activity but overactivation in Jak2 (Fig. 3). This suggests Fyn as a new downstream regulator of STAT5 phosphorylation similarly to that described in Lyn

mice. We carried out a protein alignment using ClustalW2 for Fyn and Lyn (Fig. 10). The superposed alignment gives a 62% identity and 78% sequence similarities using Blastp algorithm (Fig. 10).

Alignment Score: 54.30

Fig. 10: ClustalW2 alignment between Fyn and Lyn kinases

Previous studies have shown that Lyn targets STAT5, modulating its Tyr-phosphorylation state. The high similarity between Fyn and Lyn allow us to propose Fyn as possible new modulator of STAT5 in erythroid cells.
The reduction in STAT5 activation observed in Fyn−/− mouse erythroblasts supports this interplay and it is in agreement with previous reports in other cell types (i.e. such mast cells and CML cells)\textsuperscript{19,20}. In Fyn−/− mice, the reduction in STAT5 activation may be responsible for the microcytic anemia as previously reported in mice genetically lacking STAT5.\textsuperscript{21}

In Fyn−/− mice, the reduced efficiency of EPO signaling pathway was also indicated by increased ROS levels and cell apoptosis of the different erythroblast subpopulations (Fig. 2). The synergic effect of reduced EPO signaling and increased oxidation results in decreased GATA-1 nuclear translocation similarly to that observed in β-thal erythropoiesis.\textsuperscript{22} Indeed, the unbalance in β-globin chain synthesis with accumulation of free α-globin chains further support the functional impact of Fyn on erythroid maturation (Fig. 2).

We then explored Jak2/STAT5 pathway in early and late erythropoiesis in Fyn−/− mice. The reduction in STAT5 activity observed in both erythroblasts and erythroid progenitors (CFU-Es) indicate the critical role of Fyn in modulating the temporary dynamics of EPO-induced erythroid maturation (Fig. 3). In Fyn−/− mice, failure in response to recombinant EPO supports the proposed role for Fyn in EPO signaling cascade (Fig 4a).

To understand the role of Fyn in stress erythropoiesis, we exposed Fyn−/− mice to either PHZ or Doxorubicin. Fyn−/− mice display high sensitivity to both PHZ and Doxorubicin with a blunt response of erythropoiesis to these stressful conditions (Fig. 4b, 5). In Fyn−/− mice, increased oxidation results in Jak2 overoxidation leading to increased activity of Akt that is an important signal to ensure erythroid survival and maturation (Fig 6b).\textsuperscript{23,24} Akt intersects several pathways such as Nrf2, a redox sensitive transcriptional factor, and mTOR, the gatekeeper of autophagy.\textsuperscript{15,16} Fyn−/− mice display activation of Nrf2, resulting in up-regulation of ARE genes and the related encoded proteins for antioxidant systems (Fig. 6, 7). However, the up-regulation of these cytoprotectors is unable to counteract oxidation of Fyn−/− erythroblasts. In cell homeostasis, the prolonged oxidation might overcome autophagy, resulting in cell apoptosis.\textsuperscript{25} This seems to be the case of Fyn−/− erythroblasts where we found increased cell apoptosis (Fig. 2c). It is of note that Fyn−/− mouse erythroblasts display mTOR activation resulting in impairment of autophagy as supported by accumulation of p62. Since p62 is an
autophagy adaptor important in protein quality control system, the accumulation of p62 is generally used as a marker of blockage of the autophagic flux.\textsuperscript{25,26} Thus, we propose that the absence of Fyn might result in impairment of late phase of autophagy during erythroid maturation (Fig. 8a). In agreement, we found a reduction in \textit{in vitro} reticulocyte maturation with delayed lysosomal clearance and again accumulation of p62 in Fyn\textsuperscript{-/-} mouse reticulocytes (Fig. 6b, c). Our group has recently reported an impairment of autophagy with accumulation of p62 in both erythroblasts and red cells from patient with chorea acanthocytosis. This, further support the crucial role of autophagy in erythropoiesis.\textsuperscript{27} Since no change in mitochondrial clearance was found in Fyn\textsuperscript{-/-} \textit{in vitro} maturating reticulocytes, we might reasonably exclude alteration of mitophagy in Fyn\textsuperscript{-/-} mice. This is also supported by similar Nix protein content observed in \textit{in vitro} maturating reticulocytes from both mouse strains (data not shown).\textsuperscript{25,27}

We carried out the revision of the literature on pharmacologic activators of autophagy and erythropoiesis. (Table 4).

</table>
(2 mg/kg) in C57B6/2J mice for 3 days

- Decreased proliferation of early erythroid precursors with increased late stage erythroblasts;
- Complete block of mTOR downstream signaling pathway;
- Co-administration of PHZ (50 mg/kg) is lethal after 3 days of treatment: critical role of mTORC 1/2 signaling in response to acute hemolytic anemia.

INK128, dual mTORC1/2 inhibitor (1 mg/kg) in humanized sickle cell mice for 3 weeks

- In SCD mice:
  - Increased erythrocytes count, Hct and Hb content;
  - Reduced reticulocytosis;
  - Markedly decreased spleen size without changes in total body weight.

Sirolimus, selective mTORC1 inhibitor (5 mg/kg) in humanized sickle cell mice for 3 weeks

- In both transplanted and non-transplanted SCD mice,
  - Increased Hct and Hb, after 1 week of treatment;
  - Decreased splenomegaly;
  - Increased RBC lifespan;
  - Improved erythroid maturation;
  - Decreased iron deposition in kidney and liver;
  - Decreased stroke volume (reduced sickling/vaso-occlusive crisis).

Rapamycin, an mTOR inhibitor (4 mg/kg) in FOXO3−/− mice for 5 days/week for 2 weeks

- In FOXO3−/− mice and β-thal mice:
  - Increased Hb levels (Foxo3−/− mice and β-thal mice);
  - No major effect on total erythroblast count, but ameliorated terminal erythroid differentiation (β-thal mice);
  - Blocked cell cycle progression in immature erythroblasts (β-thal mice);
  - Amelioration of the β-globin gene expression (β-thal mice);
  - Significant reduction in EPO levels;

EPO: erythropoietin; mTOR: mammalian target of Rapamycin; PHZ: phenylhydrazine; Hct: hematocrit; Hb: hemoglobin; β-thal: β-thalassemia; SCD: sickle cell disease; RBC: red blood cell

These results suggest that autophagy plays a key role in erythroid maturation and that modulation of the autophagic process might beneficially impact diseased erythropoiesis. In our model, Rapamycin administration reduces total erythroblasts and ameliorates cellular homeostasis by reduction of oxidation (Fig. 9a, b). The activation of autophagy reduces cell apoptosis as indicated by the decrease amount of Annexin V+ cells (Fig. 9c). The restoration of the balance between apoptosis and autophagy results in decreased cellular levels of p62 (Fig. 9d). Our data indicate
that the absence of Fyn might affect autophagic lysosomal clearance system, which is particularly crucial during reticulocyte maturation.

In conclusion, we unveil the role of Fyn as a new kinase in EPO signaling cascade, increasing the complexity of EPO pathway, which already requires Jak2 as primary kinase and Lyn as additional kinase.\textsuperscript{30} In Fyn\textsuperscript{−/−} mice, the overactivation of Jak2 increases Akt function, resulting in persistent activation of Nrf2 and impairment of autophagy by mTOR activation. This results in cellular dysfunction which becomes evident when Fyn\textsuperscript{−/−} mice were exposed to stressful conditions, such as PHZ or Doxorubicin.

Future studies will be designed to further characterize the signaling pathways intersects by Fyn in normal and diseased erythropoiesis. The co-administration of Rapamycin with PHZ, will help us in dissecting the contribution of activated autophagy in response to stress erythropoiesis. In Fyn\textsuperscript{+/−} mice, other more selective inhibitors of either mTORC1 or mTORC1/2 might be tested to better understand whether the beneficial effect of Rapamycin is strictly dependent on its inhibitory effect on mTORC1 or involves other important factors in autophagy.

Since intense or persistent oxidation might block autophagy\textsuperscript{31}, we plan to treat Fyn\textsuperscript{−/−} mice with N-Acetyl-Cysteine (NAC) as exogenous antioxidant molecule.\textsuperscript{32,33}

\textbf{ABSTRACT}

Pulmonary-artery-hypertension (PAH) is a life-threatening and highly invalidating chronic disorder. Chronic oxygenation contributes to lung damage and disease progression. Peroxisiredoxin-2 (Prx2) is a typical 2-cysteine (Cys) peroxiredoxin but its role on lung homeostasis is yet to be fully defined. Here, we showed that Prx2\textsuperscript{−/−} mice displayed chronic lung inflammatory disease associated with (i) abnormal pulmonary vascular dysfunction; and (ii) increased markers of extracellular-matrix remodeling. Hypoxia was used to induce PAH. We focused on the early phase of PAH to dissect the role of Prx2 in generation of PAH. Hypoxic Prx2\textsuperscript{−/−} mice showed (i) amplified inflammatory response combined with cytokine storm; (ii) vascular activation and dysfunction; (iii) increased PDGF-B lung levels, as marker of extracellular-matrix deposition and remodeling; and (iv) ER stress with activation of UPR system and autophagy. Rescue experiments with in vivo the administration of fused-recombinant-PEP-Prx2 show a reduction in pulmonary inflammatory vasculopathy and in ER stress with down-regulation of autophagy. Thus, we propose Prx2 plays a pivotal role in the early stage of PAH as multimodal cytoprotector, targeting oxidation, inflammatory vasculopathy and ER stress with inhibition of autophagy. Collectively, our data indicate that Prx2 is able to interrupt the hypoxia induced vicious cycle involving oxidation-inflammation-autophagy in the pathogenesis of PAH.

\section{1. Introduction}

Pulmonary artery hypertension (PAH) is a life threatening highly invalidating chronic disorder \cite{[1–3]}. Although in the last decade progresses have been made in the identifications of factors involved in its pathogenesis, much still remains to be investigated in the mechanism involved in the early stage of PAH \cite{[3–5]}. Regardless of the initial event, the combination of chronic inflammation and chronic...
hypoxia promote a high pro-oxidant environment, mediating disease progression [1,2,4,6,7].

In this scenario, efficient catabolic pathways to either build-up misfolded/unfolded proteins or to clear intracellular damaged proteins are required [8–11]. Studies in different models of PAH have shown that cellular response to face the accumulation of damaged proteins is mainly through endoplasmic reticulum (ER) stress followed by the activation of autophagy to clear damaged proteins and to reduce ER stress [10,12,13]. Indeed, classic chaperones such as heat shock protein 90 and 70 (HSP) are upregulated in PAH, indicating the requirement of chaperone systems to deal with the accumulation of damaged proteins [14].

Prx2 is a typical 2-cysteine (Cys) peroxiredoxin ubiquitously expressed. Prx2 has been largely investigated in erythroid cells, where it is approved the experimental protocols. Where indicated WT and Prx2−/−

2.1. Drugs and chemicals

2.2. Mouse strains and design of the study

C57B6/2J mice as wildtype controls (WT) and Prx2−/− mice aged between 4 and 6 months both male and female were used in the present study [19,26]. The Institutional Animal Experimental Committee, University of Verona (CIRSAL) and by the Italian Ministry of Health approved the experimental protocols. Where indicated WT and Prx2−/− mice were treated with 1) N-Acetyl-Cysteine (NAC) in NaCl 0.9%, NaOH 36 mM, pH 9.4; ip) or vehicle only for 3 weeks [19,20]; 2) PEP Prx2 (in PBS) or vehicle at the dosage of 100 mg/kg/d (in NaCl 0.9%, NaOH 36 mM, pH 9.4; ip) or vehicle only for 3 weeks [19,20]; 3) N-Acetyl-Cysteine (NAC) at the dosage of 100 mg/kg/d (in NaCl 0.9%, NaOH 36 mM, pH 9.4; ip) or vehicle only for 3 weeks [19,20]; 4) N-Acetyl-Cysteine (NAC) at the dosage of 100 mg/kg/d (in NaCl 0.9%, NaOH 36 mM, pH 9.4; ip) or vehicle only for 3 weeks [19,20]; 5) N-Acetyl-Cysteine (NAC) at the dosage of 100 mg/kg/d (in NaCl 0.9%, NaOH 36 mM, pH 9.4; ip) or vehicle only for 3 weeks [19,20]; 6) N-Acetyl-Cysteine (NAC) at the dosage of 100 mg/kg/d (in NaCl 0.9%, NaOH 36 mM, pH 9.4; ip) or vehicle only for 3 weeks [19,20]; 7) N-Acetyl-Cysteine (NAC) at the dosage of 100 mg/kg/d (in NaCl 0.9%, NaOH 36 mM, pH 9.4; ip) or vehicle only for 3 weeks [19,20];

2.2.1. Bronchoalveolar lavage (BAL) measurements

BAL fluids were collected and cellular contents were recovered by centrifugation and counted by microcymetry as previously reported [27]. Percentage of neutrophils was determined on cytopsin centrifugation. Remaining BAL samples were centrifuged at 1500 × g for 10 min at 4 °C. The supernatant fluids were used for determination of total protein content [27].

2.3. Lung molecular analysis

2.3.1. Lung histology

Multiple (at least five) three-micron whole mount sections were obtained for each paraffin-embedded lung and stained with hematoxylin eosin, Masson’s trichome, and May-Grünwald-Giemsa. α-smooth muscle actin immunohistochemistry (IHC) on lungs was carried out as previously reported [27,30]. Lung pathological analysis was carried out by blinded pathologists as previously described [27,30]. Based on previous reports (18, 38), the pathological criteria for lung histopathology were as follows: i) Bronchus: Mucus: 0: no mucus; +: mucus filling less than 50% of the area of the bronchus section; ++: mucus filling more than 50% of the area of the bronchus section. (ii) Inflammatory infiltrate density: 0: less than 5 inflammatory cells per field; +: 5–30 inflammatory cells per field; ++ more than 30 inflammatory cells per field. (iii) Thrombi: 0: no thrombus; +: presence of a thrombus in one field, at magnification 250.

2.3.2. Immunoblot analysis

Frozen lung and heart from each studied group were homogenized and lysed with iced lyses buffer (LB containing: 150 mM NaCl, 25 mM bicine, 0.1% SDS, Triton 2%, EDTA 1 mM, protease inhibitor cocktail tablets (Roche), 1 mM Na3VO4 final concentration) then centrifuged 10 min at 4 °C at 12,000g. Proteins were quantified and analyzed by mono-dimensional SDS polyacrylamide gel electrophoresis. Gels were transferred to nitrocellulose membranes for immuno-blot analysis with specific antibody. Details are reported in Supplemental materials and methods [21,27,31–33]. Whenever indicated Prx2 dimerization was studied in lung from PBS perfused mice containing 100 mM NEM, using an approach similar to that reported by Kumar et al. [34].

2.3.3. RNA isolation, cDNA preparation and quantitative RT-PCR

Total RNA was extracted from tissues using Trizol reagent (Life Technologies, Monza, Italy). Synthesis of cDNA from total RNA (1 μg) was performed using Super Script II First Strand kits (Life Technologies). Quantitative RT-PCR (qRT-PCR) was performed using the SYBR-green method, following standard protocols with an Applied Biosystems ABI PRISM 7900HT Sequence Detection system. Relative gene expression was calculated using the 2ΔΔCt method, where ΔCt indicates the differences in the mean Ct between selected genes and the internal control (GAPDH). qRT-PCR primers for each gene were designed with Primer Express 2.0 (Life Technologies) (primer sequences are reported in Table 1S) [27,30].

2.4. MDA assay

MDA was determined as previously reported [35].

2.5. Evaluation of right ventricular hypertrophy and echocardiography measurements

Hearts were fixed with 10% formaldehyde for 24 h. The right ventricular (RV) free wall was separated from the left ventricular with septum (LV+S) under dissection microscope. RV and LV + S were separately weighed and used to calculate the ratios RV/(LV + S)/body weight [36]. Thoracostatic echocardiography was performed with a Vevo 2100 echocardiograph (Visual Sonic, Toronto, Canada) equipped with a 22–55 MHz transducer (MicroScan Transducers, MS500D) as previously reported [27,37].

2.6. Statistical analysis

Data were analyzed using either t-test or the 2-way analysis of
variance (ANOVA) for repeated measures between the mice of various genotypes. A difference with a P value less than 0.05 was considered significant.

3. Results

3.1. Mice genetically lacking Prx2 show lung inflammation, increased pulmonary vascular activation and extracellular-matrix remodeling

Lung histopathologic analysis showed increased peribronchial edema in Prx2-/- mice (upper panel Hematoxylin Eosin x 250) and deposits of alpha actin in vascular walls in Prx2-/- mice (lower panel Immunohistochemistry using anti alpha actin antibody x 600). B. Immunoblot analysis with specific antibodies against phospho-NF-kB (P-NF-kB), NF-kB, phospho-Nrf2 (P-Nrf2) and Nrf2 of lung from wildtype (WT) and Prx2-/- mice under normoxic condition. One representative gel from six with similar results is presented. Right panel. Densitometric analysis (DU: Density Units) of immunoblots is shown as means ± SD (n = 6); *p < 0.05 compared to wildtype. C. IL-6, IL-1b, IL-10 mRNA levels in lung tissues (normalized to GADPH) from WT and Prx2-/- mice. * p < 0.05 (WT vs Prx2-/-). Each sample (WT; Prx2-/-) is a pool from 5 mice. Representative of three independent experiments. D. Immunoblot analysis with specific antibodies against IL-6, heme-oxygenase 1 (HO-1), endothelin-1 (ET-1), superoxide dismutase (SOD-1), vascular cell adhesion molecule-1 (VCAM-1), platelet derived growth factor-B (PDGF-B) and peroxiredoxin-2 (Prx2) of lung from wildtype (WT) and Prx2-/- mice under normoxic condition. One representative gel from six with similar results is presented. Right panel. Relative quantification of immunoreactivity (DU: Density Units) of IL-6, HO-1, SOD1, ET-1, VCAM1, PDGF-B and Prx2 of lung from wildtype (WT) and Prx2-/- mice under normoxic condition. Data are shown as means ± SD (n = 6); *p < 0.05 compared to wildtype.

In Prx2-/- mice, we observed increased active form of NF-kB and Nrf2, two redox related transcriptional factors, compared to wildtype animal (Fig. 1B).

This was associated with increased lung MDA levels (Fig. 1SB) and up-regulation of the pro-inflammatory cytokines IL-6, IL-1b and IL10 that are known targets of NF-kB (Fig. 1C). We confirmed the increased expression of IL-6 by immunoblot analysis in lung from Prx2-/- mice compared to wildtype animals (Fig. 1D). The activation of Nrf2 in the absence of Prx2 was supported by the up-regulation of Nrf2 related systems such as HO-1, a vascular and lung cytoprotector, and SOD-1, a potent anti-oxidant enzyme supports (Fig. 1D) [38]. We also observed higher levels of (i) endothelin-1 (ET-1), the most potent vasoconstrictive and broncho-constrictive cytokine [30]; (ii) VCAM-1, a marker of vascular endothelial activation [27]; and (iii) PDGF-B, a known factor involved in lung extra-cellular matrix remodeling [39] (Fig. 1D).

These data link the absence of Prx2 with persistent lung inflammation, endothelial vascular activation, and extracellular matrix remodeling.
3.2. Prolonged hypoxia promotes the development of early stage pulmonary hypertension in Prx2-/- mice

Based on our previous report, showing the development of early stage PAH in a mouse model for sickle cell disease but not in wildtype mice [36], we exposed both mouse strains to hypoxia (Hy) 8% oxygen for 7 days. As shown in Fig. 2A, hypoxia induced sparse inflammatory infiltrate and an increased peribronchial edema in Prx2-/- mice (upper panel Immunohistochemistry using anti alpha actin antibody × 600) and deposits of alpha actin in vascular walls in Prx2-/- mice (lower panel Immunohistochemistry using anti alpha actin antibody × 600). B. Representative images of mitral inflow pattern recorded by Doppler echo imaging in wildtype (WT) and Prx2-/- mice under hypoxia as in Fig. 1A. Average mitral valve deceleration time (left panel) and pulmonary acceleration time (PAT) to ejection time (ET) ratio (right panel). *p < 0.05 and **p < 0.01 WT vs Prx2-/- mice; #p < 0.05 and ##p < 0.01 hypoxia vs basal by one-way ANOVA followed by Newman-Keuls Multiple Comparison test. The black dashed lines have been added to the graph to favor visual comparison between the white bars to the black bars. C. Immunoblot analysis with specific antibodies against peroxiredoxin-2 (Prx2) and thioredoxin-reductase 1 (Trdx) of lung wildtype (WT) and Prx2-/- mice under normoxia (N) exposed to hypoxia (Hy) for 10 h (10 h), 3 days (3D), 7 days (7D). One representative gel from six with similar results is presented. Densitometric analysis of immunoblots is shown in Fig. 2SA. D. Immunoblot analysis with specific antibodies against phospho-NF-kB (P-NF-kB), NF-kB, phospho-Nrf2 (P-Nrf2) and Nrf2 of lung wildtype (WT) and Prx2-/- mice under normoxia (N) and exposed to hypoxia (Hy) for 10 h (10 h), 3 days (3D), 7 days (7D). One representative gel from six with similar results is presented. Densitometric analysis of immunoblots is shown in Fig. 2SB.

This was associated with a significant increase in mitral valve deceleration time and a reduction in pulmonary acceleration time/ ejection time ratio (Fig. 2B), indicating early diastolic dysfunction and increased right ventricular systolic pressure in Prx2-/- mice. In addition, we found hypoxia induced increased expression of SOD-1 in heart from both mouse strains, but to a higher extent in Prx2-/- mice (Fig. 1SD). Hypoxia induced up-regulation of (i) VCAM-1 and ICAM-1; and (ii) atrial natriuretic peptide (ANP) was also observed in both mouse strains (Fig. 1SD).

Our findings are consistent with the development of early stage of PAH promoted by severe oxidation and amplified inflammatory response in Prx2-/- mice exposed to 7-days hypoxia.

3.3. Prx2 plays an important role as cytoprotective system against hypoxia induced PAH

In order to follow-up the generation of PAH in Prx2-/- mice, we studied both mouse strains at different time intervals between 0 to 7-days hypoxia to identify the optimal window-time to analyze
mechanism(s) involved in development of PAH. BAL protein and leukocyte count were significantly increased in Prx2−/− mice during hypoxia at 10 h, 3 days and 7 days compared to wildtype animals (data not shown).

Hypoxia markedly increased Prx2 expression in lung from wildtype mice at 10 h, 3 days and 7 days of exposure (Fig. 2C; Fig. 2SA). This was associated with time dependent increased expression of thioredoxin-reductase, a Prx2 repairing system (Trdx; Fig. 2C; Fig. 2SA). The modulation of Trdx expression during hypoxia even in the absence of Prx2, may be possible related to the fact that Trdx is part of a NADPH-dependent pathways [19,40].

In Prx2−/− mice exposed to hypoxia, we observed a rapid and sustained activation of Nrf2 in response to hypoxia, while there was a reduction in activation of NF-kb (Fig. 2D, 2SB). Otherwise, wildtype mice showed an early response of Nrf2 at 10 and 3-h hypoxia, partially overlapping the activation of NF-kb observed at 3 and 7 days hypoxia (Figs. 2D, 2SB). These data suggest that Nrf2 might be a precocious back-up mechanism in response to hypoxia, which is early activated in both mouse strains, but to a higher extent in mice genetically lacking Prx2.

Since pro-inflammatory cytokines are modulated by oxidation and participates to the development of PAH [3,41,42], we evaluated IL1b and IL6 expression in lung from both mouse strains during hypoxia. In Prx2−/− mice, IL-1β mRNA levels were significantly increased at 3 days of hypoxia compared to wildtype animals, which displayed increased IL-1β expression only at 7-days hypoxia (Fig. 3A). In Prx2−/− mice, lung IL-6 mRNA expression was significantly upregulated at 3 days of hypoxia followed by a decreased at 7 days of hypoxia to levels still higher than those observed in wildtype mice (Fig. 3B). These data support an earlier and amplified inflammatory response in Prx2−/− mice in response to hypoxia compared to wildtype animals.

We then evaluated markers of pulmonary vascular remodeling (ET-1, PDGF-B, ANP) and vascular endothelial activation (VCAM-1 and ICAM-1). As shown in Fig. 3C, ET-1 expression was increased in both mouse strains but to a higher extent in Prx2−/− mice compared to wildtype; while PDGF-B levels increased earlier, reaching higher and constant levels in Prx2−/− mice compared to wildtype during hypoxia. VCAM-1 and ICAM-1 expression was similarly increased in both mouse strains at 7 days hypoxia (Fig. 3D). Whereas, ANP levels were higher in Prx2−/− mice than in wildtype animals exposed to prolonged hypoxia (Fig. 3D).

Collectively, these data indicate that the absence of Prx2 accelerates vascular activation and extra-cellular matrix remodeling, amplifying inflammatory response and oxidation during hypoxia.

3.4. The absence of Prx2 is associated with endoplasmic reticulum (ER) stress and up-regulation of ATF6

Studies in different models of PAH have shown that hypoxia and/or PDGF-B and / or ET-1 induce severe proteins damage, which promotes endoplasmic reticulum stress (ER), triggering unfolded protein response (UPR) system [10,11,13,43]. When the accumulation of damaged proteins exceeds the ER capacity, ER stress leads to activation of autophagy as adaptive mechanism to clear accumulated misfolded/unfolded proteins [11,44]. UPR system is characterized by 3 branches: IRE, PERK and ATF6, this latter has been reported to be mainly involved in PAH [12,45]. As shown in Fig. 4A, ATF6, Chop and sXbp1 were up-regulated in lung from Prx2−/− mice under normoxia compared to wildtype animals. Whereas, GADD34 was downregulated in Prx2−/− mice compared to wildtype animals (Fig. 4A). In response to hypoxia, we observed dynamic changes of the main UPR systems: (i) ATF6; (ii) GADD34 and Chop, related to PERK and Xbp1, a component of IRE branch [10]. As shown in Fig. 4B, increased mRNA levels of both Chop and Xbp1 were observed at 10 h in Prx2−/− mice, while GADD34 was still significantly increased at 3-days hypoxia compared to normoxic Prx2−/− animals. In chronically exposed Prx2−/− mice, ATF6 and sXbp1 mRNA levels were again higher than in normoxia Prx2−/− animals (Fig. 4B). Wildtype animals show an early signs of ER stress with up-regulation of ATF6 and Xbp1 at 10-h hypoxia, with no major change in chronic hypoxia (Fig. 4B). It is of note that in lung from wildtype mice, we found Prx2 organized in multimers, possible reflecting the acquisition of chaperone like function (data not shown) [31,46,47].

These data indicate that the absence of Prx2 triggers ER stress during hypoxia, contributing to the early appearance of PAH in Prx2−/− mice.

3.5. PEP Prx2 treatment rescues prolonged hypoxia induced heart and lung inflammatory vasculopathy and prevents ER stress

To address the question whether Prx2 plays a role in lung chronic inflammatory disease, we firstly evaluated the impact of recombinant fusion protein PEP Prx2 (1.5 mg/kg/day iv; 3 weeks) to both mouse strains under room air condition. In normoxic Prx2−/− mice, PEP Prx2 treatment (i) prevented Nrf2 and NF-kb activation (Fig. 3SA); (ii) reduced HO-1 protein expression (Fig. 3SB); and (iii) decreased the levels of ET-1, VCAM-1 and PDGF-B (Fig. 3SB). No major changes were observed in wildtype animals (Fig. 3SA, 3SB). In order to evaluate whether the effects of PEP Prx2 treatment were specific of Prx2 or related to a general anti-oxidant effect, we treated both mouse strains with NAC (100 mg/kg/day for 3 weeks), a known anti-oxidant agent previously used in other in vitro and in vivo models of PAH [6,48]. No changes were present in the levels of Nrf2 and NF-kb activation in Prx2−/− mice treated with NAC, suggesting that the effects of PEP Prx2 are peculiar of Prx2 and not only related to its general antioxidative effects (data not shown).

In Prx2−/− mice exposed to 7 days hypoxia, PEP Prx2 treatment significantly reduced the hypoxia mediated diastolic dysfunction and ameliorated RVSP, as suggested by the increased in PAT/ET ratio (Fig. 4C, 4SA). In agreement, in heart from PEP Prx2 treated Prx2−/− mice exposed to 7 days hypoxia, we found a reduction of ANP expression as well as of markers of vascular endothelial activation (Fig. 4D). This was associated with a decrease in levels of SOD-1 and in oxidation of proteins from heart of hypoxic Prx2−/− mice treated with PEP Prx2 (Fig. 4SB). We found similar evidences of the beneficial effects of PEP Prx2 on lung from Prx2−/− mice exposed to prolonged hypoxia. As shown in Fig. 5A, PEP Prx2 promoted a significant reduction in chronic hypoxia induced increase of ANP, VCAM-1, ICAM-1 and PDGF-B levels compared to vehicle treated Prx2−/− animals. In addition, PEP Prx2 decreased the hypoxia induced ATF6 expression, suggesting a possible role of Prx2 as chaperone in agreement with the reduced expression of classic chaperone HSP70 and 90 (Fig. 5B).

To better understand the role of Prx2 in development of PAH, we chose to further study Prx2−/− mice at day 3 of hypoxia. This represents the turning point in the imbalance between oxidation/anti-oxidant activities and the activation of cellular defense mechanisms against cytotoxic effects of accumulation of damage proteins. Indeed, we found a significant increase in the amount of Prx2 dimers in lung from wildtype after 3 days hypoxia compared to normoxic wildtype animals (Fig. 4C), supporting the role of Prx2 as H2O2 sensor generated during hypoxia as previously shown in other models [34,49].

3.6. In Prx2−/− mice, PEP Prx2 prevents the hypoxia induced oxidative stress and reduces inflammatory vascular activation and extracellular matrix remodeling

PEP Prx2 administration prevented the hypoxia induced increased in BAL protein and leukocyte content in both mouse strains (Fig. 4SD). This was associated with a marked reduction in protein oxidation state in both mouse strains exposed to 3 days hypoxia and treated with PEP Prx2, supporting the local anti-oxidant effect of exogenous PEP Prx2 treatment during hypoxia stress (Fig. 5C). In agreement, we found that PEP Prx2 administration prevented the hypoxia induced Nrf2 and NF-kB activation in both mouse strains (Fig. 5D, 5SA). This was paralleled
by the reduction in HO-1, IL-1β, IL-6, ET-1, VCAM-1 and PDGF-B (Fig. 6A).

These data suggest that PEP Prx2 treatment during hypoxia is able to (i) decrease local pulmonary inflammation and oxidation, (ii) reduce systemic inflammatory response; (iii) beneficially affect hypoxia abnormalities in pulmonary vascular leakage; and (iv) prevent hypoxia activation of redox-sensitive transcriptional factors Nrf2 and NF-κB.

3.7. PEP Prx2 alleviates ER stress and down-regulates autophagy in Prx2−/− mice exposed to hypoxia

As shown in Fig. 6B, PEP Prx2 significantly down-regulated GADD34 in lung from Prx2−/− mice compared to vehicle treated animals. This was associated with a marked decrease in HSP70 and 90 expression in lung from both mouse strains exposed to 3 days hypoxia and treated with PEP Prx2 (Fig. 6C). This is agreement with previous reports on preventing PAH development by blocking ER stress with exogenous chemical chaperones [12].

Since a link between ER stress and activation of autophagy has been proposed to deal the accumulation of damaged proteins [10,44], we evaluated key elements of autophagy machinery and the effects of PEP Prx2 treatment in both mouse strains at 3 days hypoxia. Based on revision of the literature, we chose to analyze the expression of (i) autophagy related proteins ULk1 that is required for initiation of autophagy; (ii) LC3 I/II, a coordinator of phagosomal membranes and (iii) p62, a key cargo protein and component of inclusion bodies; and (iv) pro-caspase 3/caspase 3, involved in digestion of damaged proteins [9,50–52]. As shown in Fig. 7A, normoxic Prx2−/− mice showed increased LC3-I/II formation associated with increased expression of ULk1 and p62 compared to wildtype mice. This was associated with higher expression of pro-caspase 3/caspase 3, indicating an activation of autophagy to clear intracellular oxidative damaged proteins in Prx2−/− mice. In both mouse strains, hypoxia markedly activated autophagy as supported by increased LC3I/II expression, consumption of ULk1 and reduction of p62, suggesting a clearance of p62 positive inclusion...
bodies containing damaged proteins (Fig. 7A). It is of note that the procaspase/caspase 3 ratio was also increased in both mouse models exposed to hypoxia, but to higher extent in Prx2−/− mice compared to wildtype (Fig. 7A).

As a proof of concept that Prx2 is important in the crossroad between hypoxia induced oxidation and autophagy, we evaluated the effects of PEP Prx2 treatment on autophagy in mice exposed to 3 days hypoxia. As shown in Fig. 7A, PEP Prx2 administration rescued the hypoxia induced activation of autophagy. These data indicate that Prx2 acts as multimodal cytoprotective system and is important to prevent the development of PAH.

4. Discussion

Here, we firstly show the novel role of Prx2 as lung multimodal cytoprotector against hypoxia induced PAH. Our data also indicate that Prx2 is required in management of the physiologic oxidation in lung under room air condition. In fact, normoxic Prx2−/− mice show lung chronic inflammatory vasculopathy and vascular dysfunction, associated with activation of extracellular matrix remodeling. This is in agreement with previous studies in mouse models genetically lacking other anti-oxidant systems such as SOD-1, which show increased susceptibility to both acute and chronic lung injury [S3-S5].
Prx2−/− mice exposed to prolonged hypoxia developed signs of PAH, combined with inflammatory vasculopathy, sustained by high ET-1 expression and increased PDGF-B levels, as markers of extracellular matrix remodeling. Both molecules have been reported to accelerate the development of hypoxia-induced PAH[30,39]. The increase in ANP lung and heart expression indicates an attempt of the endogenous system to induce pulmonary vaso-relaxation and to modulate lung and heart vascular remodeling in response to hypoxia [56,57]. This was coordinated by hypoxia-induced activation of acute phase-related transcription factors: Nrf2 and NF-κB in both mouse strains. The early and higher activation of Nrf2 in Prx2−/− mice compared to wildtype animals supports the role of Nrf2 as a backup mechanism against severe oxidation in mice genetically lacking Prx2[19]. Whereas, NF-κB seemed to be more important in prolonged hypoxia for wildtype mice compared to Prx2−/− animals. The rescue experiments with PEP Prx2 corroborate the importance of Prx2 in the functional cascade activated in response to hypoxia.

In this scenario, the absence of Prx2 favors ER stress with the activation of autophagy, as important mechanisms to deal with the accumulation of cytotoxic damaged proteins triggered by hypoxia and oxidation [10,44]. ER stress activates the UPR system, which is divided into three branches: ATF6, PERK, and IRE1[10,13]. In our model, the absence of Prx2 resulted in high levels of PDGF-B and ET-1 that potentiated the hypoxia-induced activation of UPR system. The rescue experiments with PEP Prx2 corroborate the pivotal role of Prx2 in lung homeostasis.

The behavior of defensive autophagy in Prx2−/− mice exposed to...
Hypoxia is strongly linked to ER stress in the absence of Prx2. Treatment with PEP Prx2 reduced ER stress and switched-off autophagy as supported by the reduction in LC3II and accumulation of p62 (Fig. 6A). This was parallel by a decrease of hypoxia induced HSP70 and 90 expression and down-regulation of GADD34 and ATF6 levels in PEP Prx2 treated Prx2−/− mice exposed respectively to 3 and 7 days hypoxia.

Collectively, our data indicate that PEP Prx2 has a multimodal action targeting: (i) the inflammatory response; (ii) vascular and extracellular matrix remodeling, (iii) ER stress and autophagy (Fig. 7B). The correction of the imbalance between oxidation and anti-oxidant systems combined with a chaperone like function exerted by Prx2 might interrupt the vicious circle, established between oxidation-chronic inflammation with ER stress and activation of autophagy towards the generation of PAH (Fig. 7B).

In conclusion, we have firstly highlighted the novel pivotal role of Prx2 in preventing PAH induced by hypoxia. The high bio-complexity of PAH requires multimodal therapeutic approaches, which simultaneously act on different targets involved in its pathogenesis. Our data collectively support a rationale for considering Prx2 as novel therapeutic option in treatment of the early phase of PAH.

Abstract

The data presented in this article are related to the research paper entitled "peroxiredoxin-2 plays a pivotal role as multimodal cytoprotector in the early phase of pulmonary hypertension" (Federti et al., 2017) [1]. Data show that the absence of peroxiredoxin-2 (Prx2) is associated with increased lung oxidation and pulmonary vascular endothelial dysfunction. Prx2−/− mice displayed activation of the redox-sensitive transcriptional factors, NF-κB and Nrf2, and increased expression of cytoprotective system such as heme-oxygenase-1 (HO-1). We also noted increased expression of both markers of vascular activation and extracellular matrix remodeling. The administration of the recombinant fusion
protein PEP Prx2 reduced the activation of NF-κB and Nrf2 and was paralleled by a decrease in HO-1 and in vascular endothelial abnormal activation. Prolonged hypoxia was used to trigger pulmonary artery hypertension (PAH). Prx2−/− precociously developed PAH compared to wildtype animals.

### Value of the data

- Our data show that the absence of Prx2 is associated with increased lung oxidation and abnormal pulmonary vascular leakage.
- Treatment with fusion protein PEP Prx2 prevents the activation of redox related transcriptional factors and modulates anti-oxidant systems in both wildtype and Prx2−/− mice.
- PEP Prx2 significantly reduces protein oxidation in lung from exposed to prolonged hypoxia used to trigger pulmonary artery hypertension.

### 1. Data

Data show increased lung oxidation (Fig. 1A) and abnormal pulmonary vascular leakage in the absence of Prx2 (Fig. 1B). This was paralleled by the activation of redox-sensitive transcriptional factors NF-κB and Nrf2 in lung from Prx2−/− compared to wildtype animals (Fig. 2A). Indeed, in Prx2−/− we observed (i) increased expression of heme-oxygenase 1 (HO-1), a Nrf2 related cytoprotective system; (ii) markers of vascular endothelial activation such as endothelin-1 (ET-1) and vascular cell adhesion molecule -1 (VCAM-1) and (iii) marker of extracellular matrix remodeling as the platelet growth factor- B (PDGF-B) that has been recently function linked to the development of pulmonary artery hypertension (Fig. 2B). To verify the role of Prx2 as important anti-oxidant system in pulmonary homeostasis, we administrated the recombinant fusion protein PEP Prx2 at the dosage of 3 mg/Kg/d ip or vehicle for 4 weeks [1–3]. As shown in Fig. 2, PEP Prx2 significantly reduced both
NF-kB and Nrf2 activation in lung from Prx2−/− and decreased the expression of both HO-1 and markers of vascular endothelial activation or extracellular matrix remodeling. Using prolonged hypoxia to trigger pulmonary artery hypertension, we observed severe lung pathologic damage and the precocious development of pulmonary artery hypertension in Prx2−/− mice compared to wildtype animals [4–6]. This was associated with (i) marked activation of redox-related transcriptional factors; (ii) severe endoplasmic-reticulum stress with activation of the unfolded protein response (UPR) system; and (iii) activation of autophagy [1].

PEP Prx2 treatment prevented the hypoxia induced protein oxidation in mice exposed to prolonged hypoxia (7 days; Fig. 3A) and reduced the hypoxia induced increased expression of HO-1 in both mouse strains exposed to 3 days hypoxia (Fig. 3B). Collectively, these data indicate the important role of Prx2 in lung homeostasis against hypoxia, a known trigger of lung injury.

2. Experimental design, materials and methods

2.1. MDA assay

MDA assay was determined as previously reported [7,8].

2.2. Measurement of BAL protein content

2.2.1. Bronchoalveolar lavage assay

Bronchoalveolar lavage (BAL) fluids were collected and cellular contents were recovered by centrifugation and counted by microcytometry as previously reported [6,9].
2.2. Immunoblot analysis

Frozen lung from each studied group were homogenized and lysed with iced lyses buffer as previously described [3,10,11]. Gels were transferred to nitrocellulose membranes for immuno-blot analysis with specific antibodies: anti-NFkB-phospho-S536 (93H1) (Cell Signaling Technology, Leiden, NL); anti-NFkB p65 (C22B4) (Cell Signaling Technology, Leiden, NL); anti-Nrf2-phospho-S40 (Clone EP1809Y, AbCam, Cambridge, UK); anti-Nrf2 (AbCam, Cambridge, UK); anti-Heme Oxygenase-1 (HO-1) (Santa Cruz Biotechnology, Heidelberg, Germany), anti-Endothelin-1 (ET-1), vascular cell adhesion molecule-1 (VCAM-1), platelet derived growth factor-B (PDGF-B) (Cell Signaling Technology, Leiden, NL); anti-VCAM-1 (R and D Systems, Minneapolis, MN, USA); anti-PDGF-B (AbCam, Cambridge, UK); anti-GAPDH (Sigma Aldrich, Saint Louis, MO, USA) was used as loading control. Images were acquired using Image Quant Las Mini 4000 Digital Imaging System (GE Healthcare Life Sciences). Densitometric analyses were performed using the ImageQuant TL software (GE Healthcare Life Sciences) [11].

**Fig. 2.** A. Immunoblot analysis with specific antibodies against phospho-Nrf2 (P-Nrf2), Nrf2 phospho-NF-kB (P-NF-kB) and NF-kB of lung from wildtype (WT) and Prx2−/− mice under normoxic condition. One representative gel from six with similar results is presented. Right panel. Relative quantification of immunoreactivity (DU: Density Units) of phospho-NF-kB (P-NF-kB), NF-kB, phospho-Nrf2 (P-Nrf2) and Nrf2 of lung from wildtype (WT) and Prx2−/− mice under normoxic condition treated with either vehicle or penetrating peptide fusion protein peroxiredoxin-2 (PEP Prx2). Data are shown as means ± SD (n = 6). *p < 0.05 compared to wildtype; °p < 0.05 compared to vehicle treated mice. B. Immunoblot analysis with specific antibodies against heme-oxygenase 1 (HO-1), endothelin-1 (ET-1), vascular cell adhesion molecule-1 (VCAM-1), under normoxic condition treated with either vehicle or penetrating peptide fusion protein peroxiredoxin-2 (PEP Prx2). One representative gel from six with similar results is presented. Right panel. Relative quantification of immunoreactivity (DU: Density Units) of heme-oxygenase 1 (HO-1), endothelin-1 (ET-1), vascular cell adhesion molecule-1 (VCAM-1), platelet derived growth factor-B (PDGF-B) of lung from wildtype (WT) and Prx2−/− mice under normoxic condition treated with either vehicle or penetrating peptide fusion protein peroxiredoxin-2 (PEP Prx2). Data are shown as means ± SD (n = 6). *p < 0.05 compared to wildtype; °p < 0.05 compared to vehicle treated mice.
2.2.3. Measurement of lung protein oxidation

Oxidized proteins were revealed by the Oxyblot Protein Oxidation Detection Kit (EMD Millipore). In brief, the soluble protein extracts were derivatized to 2,4-dinitrophenylhydrazone (DNP) and 1 µg was loaded on 12% SDS-PAGE, blotted and incubated with an anti-DNP antibody, followed by an HRP conjugated secondary antibody. The bound activity was revealed by ECL (GE Healthcare). Oxidized proteins were revealed by the Oxyblot Protein Oxidation Detection Kit (EMD Millipore). In brief, the soluble protein extracts were derivatized to 2,4-dinitrophenylhydrazone (DNP) and 1 µg was loaded on 12% SDS-PAGE, blotted and incubated with an anti-DNP antibody, followed by an HRP conjugated secondary antibody. The bound activity was revealed by ECL (GE Healthcare) [12–14].

2.2.4. Generation of recombinant-PEP Prx2 fusion protein (PEP Prx2)

The fusion protein PEP Prx2 was generated as previously reported [2,3].

FYN KINASE IS INVOLVED IN EPO RECEPTOR SIGNALING AND IS REQUIRED TO HARMONIZE THE RESPONSE TO OXIDATION

Erythropoiesis is a complex multistep process during which committed erythroid progenitors undergo terminal differentiation to produce circulating mature red cells. Erythroid differentiation is characterized by the production of reactive oxygen species (ROS) both in response to erythropoietin (EPO) and to the large amount of iron imported into the cells for heme biosynthesis. During erythropoiesis, ROS might function as second messenger by modulating intracellular signaling pathways. Fyn, an Src kinase, has been previously reported to participate in signaling pathways in response to ROS in various cell types. Here, we explore the potential contribution of Fyn to normal and stress erythropoiesis by studying 2-4 months-old Fyn knockout mouse strain (Fyn−/−) and C57B6/2J as wild-type controls. Fyn−/− mice showed a mild compensated microcytic anemia associated with signs of dyserythropoiesis. Increased ROS levels and Annexin-V+ cells were presented in all Fyn−/− erythroblast subpopulations compared to wild-type, suggesting a possible reduction in the efficiency of erythropoietin (EPO) signaling pathway in the absence of Fyn. Indeed, in Fyn−/− erythroblasts we observed a reduction in Tyr-phosphorylation state of EPO-R associated with a compensatory activation of Jak2 without major change in Lyn activity. A reduction in STAT5 activation resulting in down-regulation of Cish, a known direct STAT5 target gene, was noted in Fyn−/− erythroblasts. This was paralleled by a reduction in GATA1 and increased HSP70 nuclear translocation compared to wild type, supporting a higher cellular pro-oxidant environment in the absence of Fyn. Using the vitro cell forming colony unit assay, we found a lower in...
CFU-E and BFU-E cells production, which once again was associated with decreased activation of EPO mediated cascade in the absence of Fyn. To explore the possible role of Fyn in stress erythropoiesis, mice were treated with either phenylhydrazine (PHZ) or doxorubicin (Doxo). Fyn−/− mice showed prolonged anemia after either PHZ or Doxo treatment with a delayed hematologic recovery compared to wild-type animals. When we analyzed the expression of a battery of ARE-genes related to oxidative response such as catalase, Gpx, heme-oxygenase 1 and peroxiredoxin-2, we noted up-regulated expression of these genes in sorted Fyn−/− erythroblasts compared to wild-type cells. In agreement, we observed increased activation of the redox-sensitive transcriptional factor Nrf2 targeting ARE-genes, whose regulation has been previously linked to Fyn. In fact, Nrf2 is switched-off by Fyn, ubiquitylated and delivered to the autophagosome by the p62 cargo protein. In Fyn−/− sorted erythroblasts, we observed (i) accumulation of p62 in large clusters; and (ii) reduction of Nrf2-p62 complex compared to wild-type cells. To address the question whether the perturbation of Nrf2-p62 system results in impairment of autophagy in the absence of Fyn, we used Lysotrack to explore late phases of autophagy. Lysosomal progression was defective in Fyn−/− reticulocytes and it was associated with accumulation of p62 during in vitro reticulocyte maturation. These data indicate that the absence of Fyn blocks the Nrf2 post-induction response to oxidation, resulting in impaired autophagy. To validate our working hypothesis, we treated Fyn−/− mice with Rapamycin, an inducer of autophagy. In Fyn−/− mice, Rapamycin treatment resulted in decrease dyserythropoiesis, ROS levels and Annexin V+ cells, associated with reduction in accumulation of p62 in Fyn−/− erythroblasts. As a proof of concept, we treated both mouse strains with PHZ with or without Rapamycin. This latter worsened PHZ induced acute anemia in wild-type mice but not in Fyn−/− animals. Collectively, our data enabled us to document a novel role for Fyn in erythropoiesis, contributing to EPO-R activation and harmonizing the Nrf2-p62 adaptive cellular response against oxidation during normal and more importantly in stress erythropoiesis.

β-thalassemia (β-thal) is one of the most common monogenetic disorders worldwide, characterized by ineffective erythropoiesis leading to a chronic, debilitating anemia associated with high morbidity and mortality. Erythroid maturation is a dynamic process tightly regulated by complex signaling mechanisms, only partially described either in normal and diseased erythropoiesis. To investigate this issue, we carried out a high throughput kinome analysis by taking advantage of Kinexus array technology (http://www.kinexus.ca), in sorted erythroid precursors from mouse model of (Hbb\(^{3th/+}\)) compared to wildtype animals. In β-thal mice, we found differential modulation of many protein kinases. Network computational analysis unveiled common as well as erythroid precursor-specific signaling mechanisms of altered erythrocyte differentiation in beta thalassemia, suggesting a selective perturbation in protein kinase/phosphatase balance in β-thal erythropoiesis.

We reasoned that balancing kinome anomalies, by increasing phosphatome activity, could normalize kinome signaling pathways, thus ameliorating erythropoiesis. We explore the expression and function of different protein phosphatase and we found reduced expression and function of protein Tyr-phosphatase receptor type, gamma (PTPRG). To investigate PTPRG role in erythropoiesis, we exploited a novel Trojan-fusion protein (TAT-ICD) we recently patented that delivers intracellularly the catalytic domain of PTPRG and up-modulates its signaling cascade, as both a research tool to map dysfunctional pathways and as a potential therapeutic agent. In β-thal mice, TAT-ICD acted on multiple abnormally activated targets identified by computational analysis. TAT-ICD significantly reduced the activation of (i) Jak2-STAT5 pathway; (ii) Bruton tyrosine kinase (BTK) that has been reported to be part
of the erythropoietin cascade; (iii) Akt that is involved in TGF-b-smad signaling pathway. This was associated with down-regulation of Erfe and Gdf11 gene expression in sorted erythroblasts from TAT-ICD treated β-thal mice. Collectively, TAT-ICD treatment resulted in amelioration of β-thal ineffective erythropoiesis, evaluated by multiple approaches, including the profile of erythroid maturation and the amount of Annexin-V*erythroid cells, reticulocyte count, circulating erythroblasts and hemolytic indices (U.S. Patent #62/109,555). The improvement of anemia was also associated with reduction in alpha aggregates and membrane bound hemichromes in circulating erythrocytes. We also found a reduction of liver and spleen iron accumulation in agreement with the beneficial effects on the hematologic phenotype. It is of note that TAT-ICD treatment did not affect either peripheral leukocyte counts or spleen lymphocyte pattern.

Our data unveil abnormalities in signal transduction pathways as new mechanism involved in β-thal erythropoiesis, and validate a novel, breakthrough, therapeutic approach to reset back to homeostatic equilibrium altered kinome in diseased erythropoiesis.
A Selective ORAL GLYT1 Inhibitor, Improves Anemia and RED CELL Survival in a MOUSE MODEL of Beta-Thalassemia

The unbalanced hemoglobin chain synthesis in beta-thalassemias leads to hemichrome-induced damage that contributes to ineffective erythropoiesis, hemolysis and reduced red cell survival. Iron overload related to ineffective erythropoiesis and abnormally low Hepcidin (Hamp), combined with the cytotoxic effects of free heme with free-alpha-chains play a key role in the increased generation of reactive oxygen species (ROS) in beta thalassemias.[2][HA³] Here we used a specific and selective inhibitor of the plasma membrane expressed glycine transporter GlyT1 (Ro4917838). Use of Ro4917838 has been associated with a dose-dependent decrease in MCH, Hb, soluble transferrin receptor, and increase in absolute reticulocytes and RBC counts in several animal species, attributed to reduced glycine bioavailability in erythroblasts and decreased heme synthesis. In rats, Ro4917838 reduces heme synthesis, and down-regulates erythroid transferrin receptor, but does not interfere with hepcidin regulation and systemic iron homeostasis (Winter et al. Exp Hematol, DOI: 10.1016/j.exphem.2016.07.003). We aimed to determine if reduced cellular availability of glycine in erythroblasts may reduce heme synthesis, and impact pathologic erythropoiesis in a mouse model for b-thalassemia. Wild-type control (WT) C57B6/2J, and beta-thalassemia Hbbth3/+ mice were treated with either vehicle or Ro4917838 at dosages of 3, 10, 30 mg/kg/d administered over 4 weeks once daily by gavage. [6]RO4917838 administration was associated with significant improvements of central hallmarks of the b-thalassemia pathology. Reduced erythrocyte destruction was seen by demonstrated by [8][WM⁹] as significant improvements in erythrocyte morphology and amelioration of hemoglobin reduction in reticulocytes. We also observed an impressively quick reduction of the circulating erythroblast count within 1 week of initiating treatment. This was also associated with decreased hemolysis biomarkers. Ro4917838 induced a significant reduction in extramedullary erythropoiesis and reduction in orthochromatic erythroblasts as well as insoluble alpha chain aggregates in circulating red cells. Red cell survival of b-thal mice treated with 30 mg/kg/day Ro4917838 significantly increased by more than 50%. CD71+ erythroid precursors significantly decreased in WT mice treated with Ro4917838 at 30 mg/kg and in b-thal mice at the dosage of 30 mg/kg/d. [10]These data suggest that Ro4917838 ameliorates anemia in a b-thalassemia mouse model and positively affects ineffective erythropoiesis and red cell survival in peripheral circulation. Ro4917838 may represent a novel therapeutic approach for the treatment of anemia in b-thalassemia patients. [1] I do see the point for beta-thalassemia, but this does not apply for all thalassemias, I mean the free alpha chains. The ROS yes, they have in common. In this sentence it seems to be that the alpha chains are culprit for ROS in all thalassemias. [HA³] I do see the point for beta-
thalassemia, but this does not apply for all thalassemias, I mean the free alpha chains. The ROS yes, they have in common. In this sentence it seems to be that the alpha chains are culprit for ROS in all thalassemias. ROS was not measured, therefore I would refrain mentioning it. No data is shown. [HA{5}ROS was not measured, therefore I would refrain mentioning it. No data is shown. I propose deletion of the PK info. Although the information is correct I don’t think this is the level of detail needed for the abstract. It may even be confusing as it is not the focus of the abstract to do a cross species comparison. [AK7]Propose deletion of the PK info. Background: β-thalassemias (β-thal) are worldwide distributed red cell disorders, characterized by ineffective erythropoiesis and reduced red blood cell (RBC) lifespan. Increased levels of reactive oxygen species (ROS) have been reported to play a key role in anemia of β thal, targeting both erythropoiesis and circulating RBCs. Pyruvate kinase (PK) is an important enzyme in the glycolytic pathway, responsible for conversion of phosphoenolpyruvate to pyruvate, with concomitant formation of the energy carrier adenosine triphosphate (ATP). As mature erythrocytes lack mitochondria, they rely almost exclusively on glycolysis to generate ATP, as well as the interlinked pentose phosphate pathway shunt to generate the reducing agent NADPH. The possible impact of PK activity on erythropoiesis is supported by evidence of ineffective erythropoiesis in human subjects with PK deficiency as well as mouse models of PK deficiency. The PK activator AG-348 has been evaluated in Phase I trials in healthy human subjects (NCT02149966) and is currently in Phase II studies in PK deficiency patients (NCT02476916). In the Phase I studies, AG-348 was shown to decrease levels of an upstream metabolite 2,3-diphosphoglycerate (2,3-DPG) and increased levels of ATP in whole blood, consistent with in vivo activation of PK.

Aims: To evaluate the impact of AG-348 on anemia and ineffective erythropoiesis in a mouse model of β thal intermedia.

Methods: Mouse strains C57B6/2J, as wildtype (WT) controls, and Hbbth3/+, as a mouse model of β-thal intermedia, were used. Female mice aged between 2-3 months were treated with either vehicle or AG-348 at 50 mg/kg bid by oral gavage. Hematologic parameters, RBC indices, morphology, and reticulocyte count were evaluated at baseline, 7, 14, 21 days of treatment. Mouse erythropoiesis was studied using the CD44/TER119 gating strategy by FACS. ROS levels and the amount of Annexin-V+ cells were evaluated in erythroblast populations. Liver iron accumulation was evaluated by Pearl's staining and expression of liver hepcidin was measured by RT-PCR.

Results: In Hbbth3/+ mice, 21 days of AG-348 treatment was associated with (i) a marked amelioration of anisopoykilocytosis; (ii) significantly increased Hb levels, MCV and MCH; (iii) a significant reduction in circulating erythroblasts (Es) and reticulocyte count; and (iv) reduction of ROS levels in circulating RBCs. In addition, AG-348 significantly decreased the amount of membrane precipitated α-globin chains and increased the amount of soluble Hb compared to the vehicle treated Hbb3th/+ group. Consistent with these findings, we observed (i) a reduction of extramedullary erythropoiesis as indicated by both a decrease in spleen weight/mouse weight ratio and total Es (CD44TER119 Fsc high cells); (ii) a significant increase in pro-Es and basophilic Es, associated with reduction in orthochromatic Es; (iii) a reduction in ROS levels of Hbb3th/+ Es and the amount of apoptotic orthochromatic Es compared to vehicle treated Hbb3th/+ mice, suggesting an amelioration of β thal ineffective erythropoiesis.. The amelioration of ineffective erythropoiesis was paralleled by a reduction in liver iron overload and up-regulation of hepcidin mRNA in liver from AG-348 treated Hbb3th/+ mice.

Summary/Conclusion: Our data show that the PK activator AG-348 beneficially affects ineffective erythropoiesis in a mouse model of β thal and might represent a novel therapeutic tool in clinical management of anemia in β thalassemic syndromes.

Background
Fyn is a member of the Src family of tyrosine kinases (SFKs) and shares high homology with Lyn that has been previously involved in erythropoiesis. Previous reports have shown that Lyn targets EPO-R/Jak2/STAT5 signaling pathway. Although progresses have been done in the knowledge of molecular mechanisms involved in normal and diseased erythropoiesis, much still remains to be investigated on signal transduction pathway during erythropoiesis differentiation and maturation.

Aims
Functional characterization of erythropoiesis in Fyn−/− mice.

Methods
Female aged between 2-4 months from C57BL/6J, as wild-type (WT) controls, and Fyn−/− mouse strains were used. Phenylhydrazine (PHZ) at 40 mg/kg or Doxorubicin at 0.25mg/kg by intraperitoneal injection were used to explore stress erythropoiesis. Hematologic parameters, red indices and reticulocyte count were evaluated as previously reported (Matte A, et al. ARS, 2015). Mouse erythropoiesis was studied using the CD44/Ter119 gating strategy by FACS. ROS levels and the amount of Annexin V cells were also evaluated in erythroblast subpopulations. In vitro colony-forming unit assay was performed to obtain CFU-Es and BFU-Es. Immunoblot analysis was carried out to study early and late erythropoiesis.

Results
Fyn−/− mice showed signs of dyserythropoiesis associated with increased total erythroblasts (CD44+TER119+FSC<sup>high</sup>), without extramedullary erythropoiesis. Fyn−/− erythroblasts showed higher ROS levels and increased amount of Annexin V cells, compared to WT, indicating increase oxidative stress and cell apoptosis. High ROS levels in erythroblasts have been described in β-thalassemic mouse erythroid cells as model of stress erythropoiesis. This has been linked with instability of GATA-1, which nuclear translocation is prevented and requires the stabilization of heat shock protein (HSP70-90). In Fyn−/− mice, we explored GATA-1/HSP70 distribution in subcellular fractions. Fyn−/− erythroblasts showed reduction in GATA-1 nuclear translocation, compared to WT. In agreement with reduced GATA-1 nuclear translocation, a marked decrease in β-globin chain synthesis, resulting in an imbalance in α/β globin chain levels, was observed in Fyn−/− mice.

To further characterize the impact of the absence of Fyn on erythropoiesis, we set up a colony-forming unit assay for CFU-E and BFU-E. The lack of Fyn resulted in a significant decrease in CFU-E and BFU-E colonies, suggesting an impairment of early erythropoiesis. Erythroid commitment and differentiation is strictly dependent on EPO-R/Jak2/STAT5 signaling pathway. The absence of Fyn resulted in a marked decrease in STAT5 activation, supported by a significant down-regulation of Cish, that is strictly regulated by STAT5 function.

Using Doxorubicin and PHZ, we found a delay in increased reticulocyte count related to either Doxorubicin or PHZ treatment, shedding new light on the role of Fyn in stress erythropoiesis. In addition, we found chronic activation of Nrf2 related to lack of its physiologic inhibitor, Fyn. Indeed, we found increased ARE-related genes such as heme oxygenase-1 (HO-1), which expression seems to become independent from heme concentration in the absence of Fyn. In fact, biliverdin reductase (BVR) that is functionally link to Nrf2 but it depends from another transcriptional factor was similar to that observed in WT mice.

Conclusions
Our preliminary data support a novel role of Fyn as both oxidative sensor and new modulator of the EPO/STAT5 pathway.
